Abstract:	<p>Early diagenesis of marine organic matter dramatically impacts Earth's surface chemistry by changing the burial potential of carbon and promoting the formation of authigenic mineral phases including carbonate concretions. Marine sediment-hosted carbonate concretions tend to form as a result of microbial anaerobic diagenetic reactions that degrade organic matter and methane, some of which require an external oxidant. Thus, temporal changes in the oxidation state of Earth's oceans may impart a first-order control on concretion authigenesis mechanisms through time. Statistically significant variability in concretion carbonate carbon isotope compositions indicates changes in shallow marine sediment diagenesis associated with Earth's evolving redox landscape. This variability manifests itself as an expansion in carbon isotope composition range broadly characterized by an increase in maximum and decrease in minimum isotope values through time. Reaction transport modelling helps to constrain the potential impacts of shifting redox chemistry and highlights the importance of organic carbon delivery to the seafloor, marine sulfate concentrations, methane production and external methane influx. The first appearance of conclusively anaerobic oxidation of methane-derived concretions occurs in the Carboniferous and coincides with a Paleozoic rise in marine sulfate. The muted variability recognized in older concretions (and in particular for Precambrian concretions) likely reflects impacts of a smaller marine sulfate reservoir and perhaps elevated marine dissolved inorganic carbon concentrations. Causes of the increase in carbon isotope maximum values through time are more confounding, but may be related to isotopic equilibration of dissolved inorganic carbon with externally derived methane. Ultimately the concretion isotope record in part reflects changes in organic matter availability and marine oxidation state, highlighting connections with the subsurface biosphere and diagenesis throughout geologic time.</p>

April 21st, 2023

Dear Editors of *Geochimica et Cosmochimica Acta*,

Please consider this revised version of the accepted manuscript “Temporal evolution of shallow marine diagenetic environments: Insights from carbonate concretions” by S.J. Loyd et al. for publication in *Geochimica et Cosmochimica Acta*.

The current draft incorporates suggested and required edits indicated by one reviewer and the executive editor. We have taken all of these into consideration and modified the manuscript accordingly. These edits are described in detail in an accompanying response to review document.

We hope this new draft is ready for publication in GCA.

Sincerely,

Sean J Loyd (on behalf of all co-authors)

Response to Review

Please find responses to reviewer comments below. Included line numbers indicate changes to the text in the revised, marked draft, where appropriate. Reviewer comments are provided in regular text, responses are provided in italics.

Executive Editor Comments:

1. Please insert a section titled "Appendix A. Supplementary Material" immediately before the references. In this section, briefly describe the contents of the supplementary file(s) associated with this paper. This text should explain to readers the information that they can find in your supplementary file(s). Consult the Guide for Authors for additional instructions.

Appendix A section has been added (lines 798-807).

2. GCA papers do not contain background or review sections. Please remove section 2. Some portions of this content may be integrated into the introduction, but such sections cannot include excessive review and much of the text should be moved. Note that Introductions are required to be a single section, they cannot contain subsections.

Former section 2 has been removed. A small amount of text has been incorporated into the introduction (lines 94-104). The Introduction remains as a single section without subsections.

3. Figure 1 also is unnecessary and should be removed. The authors may place these items in the supplement if they wish to retain the content somewhere, but they must justify their scientific purpose.

Former Figure 1 has been removed. Figure numbering has been changed accordingly.

4. The supplementary document must contain information (e.g., title and author list) on its first page indicating that it is associated with this manuscript.

This information has been added to the supplementary material.

5. Please update your references to current GCA format. Note that GCA reference format changed in mid-2022 and many reference manager software packages do not yet reflect this change.

References in the main text and supplement have been updated accordingly.

6. The resolution of some figures (e.g., Fig. 9) may need to be increased to aid in clear production.

Higher resolution pdfs for all main text figures have been uploaded as individual files (as opposed to embedded within the text document). Figure captions are provided at the end of the text document in accordance with GCA formatting requirements.

Reviewer #2:

Loyd et al. present data compilation of carbonate concretions through time and discuss factors controlling the abundance and isotopic compositions of carbonate concretions. Carbonate concretion is an important archive of paleoenvironment, and provide unique proxies for ancient diagenetic settings. In this paper authors show that amplified variability in concretion carbon isotopes coincides with proposed increases in organic carbon export and marine sulfate concentrations. It cannot be denied that the compiled data is of great value and allow us to better explore diagenetic processes. However, there is an alternative interpretation for the observed patterns. C isotopes of modern carbonate concretions show a wide range of variation, probably reflecting the environmental and diagenetic heterogeneity. Thus, could the small range of variation of earlier data result from a limited sampling locality? Obviously, Phanerozoic has higher occurrences of carbonate concretions than Precambrian. At least most intervals in Precambrian have only a few occurrences. How can we rule out this possibility? Overall, it's a well written manuscript, but authors should justify the unbiased data set. I would be happy to see it being published at GCA once my concern has been addressed.

This is a valid point. Text has been added to section 4.4. Evolving carbon isotope distribution in shallow diagenetic environments throughout Earth history (lines 490-495) that acknowledges the lack of data in the Precambrian and stresses that additional data may provide more insight.

47 **Abstract**

48 Early diagenesis of marine organic matter dramatically impacts Earth's surface
49 chemistry by changing the burial potential of carbon and promoting the formation of
50 authigenic mineral phases including carbonate concretions. Marine sediment-hosted
51 carbonate concretions tend to form as a result of microbial anaerobic diagenetic reactions
52 that degrade organic matter and methane, some of which require an external oxidant.
53 Thus, temporal changes in the oxidation state of Earth's oceans may impart a first-order
54 control on concretion authigenesis mechanisms through time. Statistically significant
55 variability in concretion carbonate carbon isotope compositions indicates changes in
56 shallow marine sediment diagenesis associated with Earth's evolving redox landscape.
57 This variability manifests itself as an expansion in carbon isotope composition range
58 broadly characterized by an increase in maximum and decrease in minimum isotope
59 values through time. Reaction transport modelling helps to constrain the potential impacts
60 of shifting redox chemistry and highlights the importance of organic carbon delivery to
61 the seafloor, marine sulfate concentrations, methane production and external methane
62 influx. The first appearance of conclusively anaerobic oxidation of methane-derived
63 concretions occurs in the Carboniferous and coincides with a Paleozoic rise in marine
64 sulfate. The muted variability recognized in older concretions (and in particular for
65 Precambrian concretions) likely reflects impacts of a smaller marine sulfate reservoir and
66 perhaps elevated marine dissolved inorganic carbon concentrations. Causes of the
67 increase in carbon isotope maximum values through time are more confounding, but may
68 be related to isotopic equilibration of dissolved inorganic carbon with externally derived
69 methane. Ultimately the concretion isotope record in part reflects changes in organic

70 matter availability and marine oxidation state, highlighting connections with the
71 subsurface biosphere and diagenesis throughout geologic time.

72

73 **1. INTRODUCTION**

74 Carbonate concretions are isolated zones of relatively high cement content in sediments
75 and sedimentary rocks (Coleman, 1993). These precipitates can exhibit textural and
76 compositional characteristics that indicate initial formation within shallow sediments.
77 Shallow formation indicators include deflection of external lamination (Raiswell, 1971),
78 preservation of delicate primary sedimentary features (such as thin walled shells and
79 macrofauna carcasses) (Allison and Pye, 1994; Blome and Albert, 1985; Bramlette, 1946;
80 El Albani et al., 2001; Heimhofer et al., 2017; Martill, 1988), evidence of biological
81 interaction by burrowing organisms (Bjørlykke, 1973; Hesselbo and Palmer, 1992;
82 Savrda and Bottjer, 1988), erosional exhumation (Hesselbo and Palmer, 1992) and low
83 proxy-based formation temperatures (Dale et al., 2014; Loyd et al., 2012). Therefore,
84 carbonate concretions can result (at least initially) from relatively shallow diagenetic
85 processes that are intimately related to the chemical composition of marine bottom waters
86 and the availability of organic matter delivered to the sediment-water interface. The
87 geochemistry of Earth's marine environments has experienced significant temporal
88 variability in part associated with an overall increase in oxidation state (Lyons et al.,
89 2014), associated fluctuations in marine chemistry (Canfield, 1998) and changes in
90 organic carbon export (Krause et al., 2022; Krissansen - Totton et al., 2021; Planavsky et
91 al., 2022) and organic matter composition (Brocks et al., 2017). In particular, variable

92 organic carbon delivery to the seafloor and marine oxidant abundances (see below) likely
93 impacted shallow diagenetic processes related to remineralization.

94 Marine sediment-hosted carbonate concretions seem to form in association with
95 reactions that involve the microbial degradation of particulate organic matter and/or
96 methane (Irwin et al., 1977). Of these reactions, those considered most important for
97 concretion formation are iron reduction, organotrophic sulfate reduction, methanogenesis
98 and the anaerobic oxidation of methane (AOM) (Claypool and Kaplan, 1974; Coleman,
99 1993; Irwin et al., 1977; Orphan et al., 2004). The carbon isotope composition of
100 porewater DIC ($\delta^{13}\text{C}_{\text{DIC}}$) is impacted by the relative contributions of these pathways
101 wherein organic matter and methane oxidation reactions cause porewater $^{13}\text{C}_{\text{DIC}}$ depletion
102 and methanogenesis causes porewater $^{13}\text{C}_{\text{DIC}}$ enrichment. The magnitude of isotope
103 enrichments and depletions is dictated by oxidant supply and reduced carbon source
104 (organic matter or methane), among other factors (e.g., Meister et al., 2019). Carbonate
105 concretions inherit the carbon isotope composition of porewater DIC owing to minimal
106 isotope fractionation during carbonate precipitation (Emrich et al., 1970; Ohmoto and
107 Rye, 1979). Thus, concretion carbon isotope compositions and can be used to track
108 carbon-phase reactants (organic matter or methane) and/or reaction pathways of shallow
109 marine diagenetic environments through time.

110 Here, carbonate concretion abundance and carbon isotope data (consisting of both
111 new and previously reported data) are used to characterize ancient marine shallow
112 diagenetic environments. These data are assessed through a transient reaction transport
113 model to explore potential impacts of contemporaneous environmental changes.
114 Ultimately, we show that amplified variability in concretion carbon isotope signatures

115 coincides with proposed increases in organic carbon export and marine sulfate
116 concentrations, implicating these factors as important for diagenetic carbonate
117 mineralization throughout geologic time. Modeling results suggest that external methane
118 inputs are likely required to generate severe ^{13}C depletions in concretionary carbonate.
119 Elevated marine dissolved inorganic carbon (DIC) contents may also play a role by
120 muting porewater isotope variability during much of the Precambrian. In addition, we
121 identify potentially counterintuitive coincident changes in methanogenesis-driven
122 diagenesis during the Phanerozoic.

123

124 **2. METHODS**

125 Marine sediment-hosted carbonate concretion occurrence and carbonate carbon
126 isotope composition ($\delta^{13}\text{C}_{\text{con}}$) data (~5,000 data points from ~170 units) were primarily
127 compiled from published reports. New $\delta^{13}\text{C}_{\text{con}}$ data were collected from select time
128 periods where isotope data have not been reported (see Supplementary Tables 1, 2). Host
129 rock formation name, age, and lithology, and concretion mineralogy, crystallographic
130 habit (for septarian concretions), carbon and oxygen isotope data were also collected
131 (Supplementary Tables 1, 2 and 3), as available. Similar information provided for
132 authigenic carbonates recovered from siliciclastic marine sediments is provided for
133 comparison (Supplementary Table 4). Most new concretion data were generated from
134 powders of slabbed samples using a Dremel® rotary tool fitted with a 3-mm carbide drill
135 bit. Triplicate 5-7 mg splits of concretion powders were dissolved in 10% phosphoric
136 acid in sealed and evacuated exetainer vials. The carbon isotope composition of produced
137 CO_2 was determined using a G2121-i Picarro® Cavity Ringdown Spectrometer (CRDS)

138 via introduction through an Automate® carbonate preparation device. Limited additional
139 new carbon isotope data from the Chuar Group (nine data points) were generated using a
140 VG Instruments PRISM II isotope ratio mass spectrometer after sample dissolution in a
141 common acid bath at 90°C. Isotope compositions reported in the typical delta (δ) notation
142 in permil (‰) versus the VPDB standard. Isotope values were determined by comparison
143 with international [IAEA NBS-18 ($\delta^{13}\text{C} = -5.014\text{‰}$, $\delta^{18}\text{O} = -23.2\text{‰}$), Carrara Marble
144 ($\delta^{13}\text{C} = +2.46\text{‰}$, $\delta^{18}\text{O} = -2.37\text{‰}$), NIST SRM 915B ($\delta^{13}\text{C} = -8.53$)] and laboratory
145 [CRCP90 ($\delta^{13}\text{C} = -4.13\text{‰}$), CRC200 ($\delta^{13}\text{C} = +2.12\text{‰}$), WD-1A ($\delta^{13}\text{C} = -42.61\text{‰}$)]
146 standards. New carbon isotope data reproducibility was better than $\pm 1.0\text{‰}$ (2 s.d.).

147 Statistical parameter estimation of the mean, variance, minimum, maximum and
148 range of carbon isotope data was accomplished via bootstrapping (Efron, 1979) across
149 select time periods (Supplementary Table 5). Biases in estimating extrema were
150 simulated empirically from repeated resampling, and then applied to adjust distributions
151 for parameter estimation of maximum and minimum values (Efron, 1982). Confidence
152 intervals (95%) for each numerical summary across the selected time periods were
153 generated via the bootstrap empirical distributions, as were pairwise statistical hypothesis
154 tests between each pairwise combination of selected time periods.

155 The factors that control potential ranges in carbon isotope compositions were
156 evaluated using a previously described transient reaction transport model (Meister et al.,
157 2013; Meister et al., 2019). This model was developed in part to constrain transport and
158 biogeochemical impacts on isotope compositions of the dominant carbon-containing
159 porewater phases. Marine sulfate concentrations, organic carbon content at the sediment-
160 water interface, external methane delivery, isotope fractionation during methanogenesis

161 and marine DIC contents were varied to explore impacts on porewater DIC isotope
162 compositions. Here, complete ranges in porewater $\delta^{13}\text{C}_{\text{DIC}}$ values (including maxima and
163 minima) are explored without predicting specific depths of carbonate authigenesis (in
164 contrast to Laakso and Schrag (2020)). The modelled porewater isotope compositions are
165 thus reflective of all of the possible concretion isotope compositions, resolving potential
166 uncertainties in mineralization depth (e.g., Meister et al., 2019). Model inputs and
167 parameterizations are provided in the Supplementary Materials (“Modelling Approach”),
168 as is a diagram demonstrating how maximum and minimum values were determined
169 (Supplementary Figure 1). Model results are compared to the ancient concretion carbon
170 isotope record to identify potential drivers of temporal variability, they are not intended
171 to recreate specific intervals of the record.

172

173 **3. RESULTS**

174 Carbonate concretions have been identified in 379 geologic formations. Of these
175 units, carbon isotope data have been compiled or generated from 173, representing ~ 46%
176 $\delta^{13}\text{C}_{\text{con}}$ coverage. The age distribution of carbonate concretions is not uniform; the vast
177 majority have been identified in units younger than 600 Ma (Figure 1). An exception to
178 this broad temporal trend is a relatively short-lived, concretion-abundant interval between
179 ~2150 to 1750 Ma (Figure 2b). Within the Phanerozoic, concretion occurrence generally
180 increases (aside from a few exceptions) up to the modern (Figure 1c). As has been
181 recognized in a previous compilation (Mozley and Burns, 1993) concretions mostly occur
182 within shale hosts (Figure 2a) and calcite represents the dominant mineralogy (Figure
183 2b).

184 Carbon isotope compositions range from -54.0 to $+32.5\text{‰}$ for the entire data set.
185 Absolute $\delta^{13}\text{C}_{\text{con}}$ values provide only limited insight into concretion formation
186 mechanisms. These data must be corrected to account for the contemporaneous seawater
187 $\delta^{13}\text{C}$ value, which represents the starting condition that is subsequently modified
188 by shallow diagenetic processes. This correction is relatively unimportant for Cenozoic
189 concretions because seawater $\delta^{13}\text{C}$ does not significantly deviate from 0‰ . However, a
190 growing body of primary carbonate (i.e., non-diagenetic) carbon isotope data suggests
191 that seawater $\delta^{13}\text{C}$ was significantly different in earlier time periods (in particular during
192 intervals within the Proterozoic), in some cases reaching values as high as $+11$
193 (e.g., Maheshwari et al., 2010) to as low as -12‰ (e.g., Halverson et al., 2005). In order
194 to account for changes in seawater carbon isotope compositions, the quantity $\Delta^{13}\text{C}_{\text{con-sw}}$ is
195 defined as $\Delta^{13}\text{C}_{\text{con-sw}} = \delta^{13}\text{C}_{\text{con}} - \delta^{13}\text{C}_{\text{sw}}$, where $\delta^{13}\text{C}_{\text{sw}}$ is the contemporaneous seawater
196 carbon isotope composition as determined by either 1) the primarily Phanerozoic curve of
197 Veizer et al. (1999) or 2) stratigraphically nearby non-diagenetic carbonate beds. The
198 $\Delta^{13}\text{C}_{\text{con-sw}}$ parameter presented in Figure 4 thus reflects specific diagenetic pathways more
199 directly than $\delta^{13}\text{C}_{\text{con}}$. Uncertainties related to the primary carbonate $\delta^{13}\text{C}$ value and
200 temporal variability in isotope fractionation associated with organic matter production
201 (e.g., isotopic differences between contemporaneous marine DIC and organic carbon
202 varying between ~ 30 and 25‰ , Kump and Arthur, 1999) are accounted for by the gray
203 solid and dashed bands in Figure 3.

204 Values of $\Delta^{13}\text{C}_{\text{con-sw}}$ exhibit significant changes since ~ 2800 Ma (Figure 3), as
205 outlined below.

206

- 207 • Archean concretion samples from ~2800, 2603 and 2600 Ma units yield
208 $\Delta^{13}\text{C}_{\text{con-sw}}$ values that range from +9.9 to +15.0‰, -4.5 to +1.8‰ and +0.9
209 to +2.4‰, respectively.
- 210 • Early Proterozoic concretions (of the ~2150 to 1750 Ma interval discussed
211 above) show $\Delta^{13}\text{C}_{\text{con-sw}}$ values that range from -24.5 to +1.4‰. ~1400 Ma
212 concretions express $\Delta^{13}\text{C}_{\text{con-sw}}$ from -1.1 to +1.9‰.
- 213 • Concretions from a single middle Neoproterozoic site (~745 Ma) exhibit
214 $\Delta^{13}\text{C}_{\text{con-sw}}$ values ranging from -15.6 to -7.9‰.
- 215 • Late Neoproterozoic (~560 and 555 Ma) carbonate concretions exhibit
216 $\Delta^{13}\text{C}_{\text{con-sw}}$ values from -3.5 to +5.4‰.
- 217 • Cambrian to Devonian (542-360 Ma) concretions display an increased
218 range in $\Delta^{13}\text{C}_{\text{con-sw}}$, with values extending from ~ -25.3‰ to +24.5‰.
- 219 • Younger concretions within Carboniferous to Permian sedimentary rocks
220 express $\Delta^{13}\text{C}_{\text{con-sw}}$ values extending from -54.6 to +9.5‰.
- 221 • Triassic to Holocene concretions yield $\Delta^{13}\text{C}_{\text{con-sw}}$ values ranging from -
222 55.7 to +31.5‰.

223

224 For comparison, marine sedimentary authigenic carbonate data (compiled in
225 Supplementary Table 4, after Loyd and Smirnoff (2022)) are also provided. Note that
226 sedimentary authigenic carbonates characterized as “modern”, may rather have formed at
227 any time since the ages of the host sediment (host sediment ages provided in
228 Supplementary Table 4). Similarly, carbonate concretions must have formed after
229 deposition of the host rock. However, given that these precipitates form relatively soon

230 after deposition, concretion ages are here approximated as the same as their host
231 sediment. Means, minima, maxima and ranges are provided for the above age groupings
232 in Figure 4; histograms are displayed in Supplementary Figure 2, and statistical similarity
233 analyses are provided in Supplementary Table 5.

234 As with primary carbonate phases, concretions may be altered by later diagenetic
235 processes that overprint original carbon isotope compositions as often indicated by ^{18}O -
236 depleted compositions (Bojanowski et al., 2014; Gross and Tracey Jr, 1966; Seewald,
237 2003). To screen for potential late diagenetic impacts on the temporal record, plots
238 limited to samples expressing oxygen isotope compositions $> -10\text{‰}$ and $> -5\text{‰}$ have
239 been generated (Supplementary Figure 3). These plots express similar trends as the
240 complete record, suggesting that later diagenetic alteration does not strongly influence the
241 broad temporal trends in $\Delta^{13}\text{C}_{\text{con-sw}}$.

242

243 **4. DISCUSSION**

244 The concretion occurrence and carbon isotope data presented here provide a more
245 detailed picture of a temporal variability hypothesized by previous researchers (Melezhik
246 and Fallick, 1996). The potential controls of this distribution are discussed below. Firstly,
247 the quantities of concretion-bearing units and preserved marine sedimentary formations
248 are compared to determine if variability can be explained simply by changes in the
249 amount of rock preserved. Then, the major shifts in concretion carbon isotope
250 composition are assessed in the context of potential controls on early marine diagenesis
251 and mineralization.

252

253 **4.1. Insights from the concretion record**

254 The ability to assess the evolution of Earth-surface environments is increasingly
255 challenging as we move back in time due to the limited preservation of older rocks. In
256 addition, ongoing research shows that the mass of preserved sedimentary rock is not
257 readily explained by erosive processes alone. Instead, changes in the Earth-surface
258 system have likely impacted the production of sedimentary rock through time (Husson
259 and Peters, 2018; Ronov et al., 1980). Reconstructions of the temporal abundance of
260 passive margins (Bradley, 2008) and the quantity and volume of marine sedimentary rock
261 formations (preserved on the North American continent) correlate with the quantity of
262 concretion-bearing units (Supplementary Figure 4). Therefore, an environmental signal
263 cannot be confidently identified even though a clear temporal change in concretion-
264 containing units is evident. The concretion abundance record may also be obscured by
265 reporting biases in the literature, the dominant data source for this compilation. As a
266 result, the remaining discussion focuses on concretion carbon isotope data ($\Delta^{13}\text{C}_{\text{con-sw}}$)
267 and potential controls on its variability.

268 The carbon isotope composition of a carbonate concretion is inherited from the
269 porewater DIC from which it precipitates. Since there is only minimal isotope
270 fractionation associated with carbonate mineral production (Emrich et al., 1970; Ohmoto
271 and Rye, 1979), carbonate concretions provide a unique proxy for ancient diagenetic
272 settings. The carbon isotope composition of DIC in porewater reflects a mixture of
273 carbon derived from seawater, the oxidation of organic matter and the oxidation of
274 methane. In addition, methanogenesis exhibits a significant isotope fractionation
275 (Whiticar, 1999) that can further impact porewater DIC. The ranges in isotope

276 composition expressed in marine sediment porewaters result from the relative importance
277 of these different reactions in addition to the transport of carbon-containing reactants and
278 products (Zeebe, 2007). Oxidation- and organic matter-dependent reactions appear to
279 typify much of Earth history, as evidenced by the widespread occurrence of negative
280 values of $\Delta^{13}\text{C}_{\text{con-sw}}$. These reactions require external reactant(s), potentially including
281 aqueous sulfate and particulate iron oxide, and organic matter and/or methane carbon
282 sources. A growing body of research provides insight into the relative temporal
283 abundances of some of these phases. The following discussion explores reactant
284 variability and then connects these trends to specific characteristics of the $\Delta^{13}\text{C}_{\text{con-sw}}$
285 record to evaluate the evolution of marine diagenetic environments.

286

287 **4.2. Organic matter as a carbon source for carbonate precipitation**

288 The dominant concretion-forming mechanisms in marine sediments involve the
289 anaerobic degradation of organic matter or methane (Claypool and Kaplan, 1974;
290 Coleman, 1993; Irwin et al., 1977). Methane primarily forms by the degradation of
291 organic matter, either directly through fermentation reactions or indirectly through the
292 reduction of carbon dioxide derived from organic matter (Koyama, 1963; McCarty,
293 1964). Therefore, all of the major reaction pathways that lead to concretion
294 precipitation involve organic matter in one way or another.

295 The amount of marine carbon buried as organic matter has changed through time
296 (Figure 5), partially in concert with shifts in the oxidation state of Earth's surface (Krause
297 et al., 2022; Krissansen - Totton et al., 2021; Planavsky et al., 2022). Our ability to assess
298 carbon burial relies primarily on temporal changes in the carbon isotope compositions of

299 primary marine carbonates, which approximately record the isotope composition of
300 oceanic DIC at the time of deposition (Schidlowski et al., 1975). Assuming that marine
301 carbonate $\delta^{13}\text{C}$ changes reflect steady-state oceanic inorganic carbon budgets, increases
302 correspond to enhanced organic carbon burial whereas decreases reflect increased organic
303 carbon destruction (i.e., oxidation) (Kump and Arthur, 1999). Although the $\delta^{13}\text{C}$
304 composition of limestones and dolostones preserved in the geologic record may not
305 faithfully record original marine conditions (e.g., Knauth and Kennedy, 2009), long-lived
306 and global positive carbon isotope excursions are difficult to explain without invoking
307 primary marine drivers. In particular, the ~2.3 to 2.1 Ga Lomagundi excursion
308 corresponds to a large $\sim +10\%$ carbonate carbon isotope swing (e.g., Schidlowski et al.,
309 1976) thought to be related to massive deposition of organic matter and an increase in
310 atmospheric O_2 (e.g., Eguchi et al., 2020; Karhu and Holland, 1996). Although the
311 Lomagundi positive isotope excursion has been interpreted as a diagenetic signal related
312 to methane production (Hayes and Waldbauer, 2006), contemporaneous trends in sulfur
313 and sulfur isotope geochemistry are more parsimoniously interpreted as consistent with a
314 primary origin (Planavsky et al., 2012). The Lomagundi event overlaps with the
315 beginning of the concretion-abundant interval between ~2.15 to 1.75 Ga (Figure 1a, b)
316 (Melezhik and Fallick, 1996). In addition to enhanced organic matter burial,
317 contemporaneous changes in the redox state of the oceans at this time may have yielded
318 complementary conditions required to stimulate sedimentary diagenesis, such as the
319 introduction of other oxidants to Earth's surface environment (see section 4.3 below).

320 Similar, long-lived primary carbonate positive $\delta^{13}\text{C}$ values ($\geq +5\%$) occur
321 between glacial intervals in the post-~800 Ma Cryogenian Period (Halverson et al.,

322 2005). These ^{13}C -enriched values are likewise interpreted to represent the enhanced
323 burial of organic matter (Derry et al., 1992; Des Marais et al., 1992) and recent modeling
324 results support these findings (Kipp et al., 2021; Krause et al., 2022; Krissansen - Totton
325 et al., 2021; Planavsky et al., 2022). Beginning about the same time (~750 Ma) and
326 extending toward the Proterozoic–Cambrian boundary, a transition in clay mineral
327 production may have facilitated enhanced burial of organic matter (Kennedy et al., 2006;
328 Kennedy et al., 2002). However, the direct impacts of this transition on atmospheric
329 oxygen contents have been challenged (Tosca et al., 2010). In addition, labile organic
330 matter that is buried in clay-rich sediments can be protected from degradation (Keil et al.,
331 1994), complicating the ability to predict potential impacts of secular changes in clay
332 production on shallow diagenetic environments.

333 Temporal variability in the total organic carbon (TOC) contents of marine shales
334 also provides support for fluctuating organic carbon burial (Och and Shields-Zhou, 2012;
335 Sperling and Stockey, 2018). Importantly, TOC contents increase significantly across the
336 Neoproterozoic–Cambrian boundary and remain relatively high throughout the
337 Phanerozoic (Sperling and Stockey, 2018) as also supported by modeled reconstructions
338 of organic matter burial rates (Krause et al., 2022; Krissansen - Totton et al., 2021;
339 Planavsky et al., 2022). Shallow-marine diagenesis may have been stimulated as a result
340 of this high organic carbon burial rate.

341 Recent work has also revealed a profound shift in the nature of marine organic
342 matter between the Cryogenian “Snowball Earth” glacial intervals (~659 to 645 Ma).
343 Biomarker data suggest a transition from a dominantly bacterial to a bacterial and
344 eukaryotic marine planktonic biosphere (Supplementary Figure 5) (Brocks et al., 2017).

345 This expansion in marine biosphere diversity may have heralded contemporaneous
346 changes in organic matter reactivity. Organic matter reactivity impacts the efficiency of
347 remineralization (e.g., Burdige, 2007) and can influence degradation pathway (Meister et
348 al., 2013). However, the relationship between organic matter source (eukaryotic versus
349 non-eukaryotic) and general reactivity remains poorly understood. Therefore, the addition
350 of significant eukaryotic biomass may or may not have increased the reactivity of organic
351 matter and thus stimulated shallow diagenesis. The record of carbonate concretions since
352 ~659 to 645 Ma exhibits its own interesting trends, perhaps related to two subsequent
353 biological transitions, the appearance and proliferation of metazoans and land plants
354 (Supplementary Figure 5).

355 Partially decayed carcasses of animals, including bones and calcium carbonate or
356 phosphate shells, sometimes occur within carbonate concretions (El Albani et al., 2001;
357 Gaines et al., 2005; Yoshida et al., 2015). Such materials may have provided triggers for
358 localized remineralization and carbonate precipitation since the latest Neoproterozoic.
359 The large accumulation of organic matter associated with decaying animal carcasses
360 provides a local source for anaerobic degradation processes that can cause focused
361 alkalinity increase and thus facilitate carbonate formation (e.g., Duck, 1995). Inorganic
362 mineral phases (shell calcite, aragonite, or phosphate and bone) can also provide
363 nucleation sites for precipitation due in part to the reduced thermodynamic hurdles
364 related to mineral formation on preexisting crystalline materials (Berner, 1980;
365 Sunagawa, 1994).

366 The arrival of extensive (plant) terrestrial ecosystems during the Silurian
367 (Supplementary Figure 5) and their expansion thereafter (Gibling and Davies, 2012;

368 Kenrick and Crane, 1997) likely resulted in a more substantial delivery of exogenous
369 organic matter to the oceans. Such remains occur in marine sediments of the Phanerozoic
370 (Sackett et al., 1974). Raiswell and Berner (1986) have demonstrated a shift toward
371 higher C/S ratios in normal marine shales by the Middle Devonian, consistent with
372 increased delivery of terrestrial organic matter (TOM) thereafter. Remineralization of this
373 TOM could promote carbonate concretion authigenesis. Indeed, modern TOM is thought
374 to provide a significant portion of the total organic carbon budget, particularly in coastal
375 marine sediments (Burdige, 2005; Schlünz and Schneider, 2000). However, TOM may be
376 less reactive than marine organic matter (Aller et al., 1996; Burdige, 2005; Hedges et al.,
377 1997), potentially obscuring the potential impacts of increased delivery. Regardless, such
378 a fundamental shift in carbon sources to marine sediments is likely to have impacted
379 shallow marine diagenetic processes in shelf and slope depositional settings.

380

381 **4.3. Oxidant availability and its influence on organic matter remineralization**

382 Diagenetic processes in shallow marine sediments (including concretion
383 formation) are impacted by the abundance of organic carbon (Arndt et al., 2013), the
384 availability and nature of which has likely changed through geologic time (see above).
385 Remineralization reactions may or may not require additional external oxidant and thus
386 the fate of buried organic matter is variably tied to oxidant availability. The temporal
387 variability of select oxidants, including sedimentary iron oxide and marine sulfate
388 contents (recognized as important in organic matter remineralization and carbonate
389 authigenesis) is discussed in this section.

390 The idea that Earth’s surface has experienced progressive oxygenation is widely
391 accepted. The structure of this oxygenation however, remains a topic of considerable
392 debate. In addition, progressive oxygenation likely impacted the abundances of specific
393 oxidants through time differently. These oxidant budgets in turn likely imparted a first-
394 order control on sedimentary diagenesis of marine environments by stimulating oxidative
395 degradation of organic matter and methane. The temporal evolutions of oxygen and
396 oxidant availability are outlined below.

397

398 4.3.1 Oxygen (O₂)

399 Atmospheric oxygen concentrations likely provide a first-order control on the
400 oxidation state and oxidant capacity of surface environments (both terrestrial and
401 marine). The oxygen content of the atmosphere is thought to have increased as a result of
402 two major oxygenation events. The first of these corresponds to the ~2.5–2.3 Ga Great
403 Oxidation Event (GOE) and is at least casually linked to photosynthetic O₂ buildup
404 (Holland, 2002). This earlier oxygen increase, however, was probably not permanent,
405 terminating with a return to lower oxygen conditions (Bekker and Holland, 2012; Partin
406 et al., 2013). The second increase in oxygen content is thought to have occurred during
407 the Late Neoproterozoic to early Cambrian (Chen et al., 2015; Sahoo et al., 2012; Scott et
408 al., 2008), may have resulted in the ventilation of portions of the deep ocean and heralded
409 the oxygen-rich conditions exhibited today (Lyons et al., 2014). Phanerozoic atmospheric
410 oxygen contents have also fluctuated, albeit at a higher level (between ~10-100% present
411 atmospheric level) (e.g., Berner and Canfield, 1989; Lenton et al., 2018).

412 Despite increasing oxygen concentrations in Earth's atmosphere, the oxidation
413 state of the oceans has exhibited its own complexity, driven in part by the evolving
414 atmospheric boundary condition (Canfield, 1998; Lyons et al., 2009). Prior to the GOE
415 Earth's oceans were predominantly ferruginous (iron(II)-rich) at all depths. After the
416 GOE and until the Proterozoic-Phanerozoic boundary, the redox structure shifted to
417 include oxic and/or sulfidic shallow/mid-depth waters over a persistently ferruginous
418 deep ocean, reflecting in part the delivery of sulfate by oxidative weathering on land and
419 its subsequent reduction to hydrogen sulfide in the water column (Lyons et al., 2009;
420 Planavsky et al., 2011; Poulton et al., 2010). In contrast, generally oxygenated oceans
421 typify the Phanerozoic, with low oxygen and sulfidic marine environments restricted to
422 near-shore, productive and/or restricted settings (Anderson and Devol, 1973; Jacobs et
423 al., 1985; Price and Calvert, 1973; Skei, 1983). These marine transitions are relatively
424 coarse; the fine-scale structure of the redox state of the oceans is potentially much more
425 complex and remains the topic of considerable debate (Lyons et al., 2014). Although the
426 *general* transitions in atmospheric and ocean oxidation state are widely accepted, bottom
427 water concentrations of oxidized phases other than oxygen (including iron oxides and
428 dissolved sulfate) are less well constrained. Oxidant availability at the sediment–water
429 interface impacts the degradation potential of sedimentary organic matter and methane
430 and thus provides a first order control on shallow marine diagenesis.

431

432 4.3.2 Particulate Iron Oxide

433 Iron oxide minerals provide an attractive electron acceptor for organic matter and
434 methane oxidation and subsequent concretion precipitation. Iron reduction metabolisms

435 are thought to be relatively ancient, as indicated by iron isotope compositions in rocks as
436 old as ~3.8 Ga (Supplementary Figure 5) (Craddock and Dauphas, 2011). A compilation
437 of speciation data for shale-hosted iron provides insight into the relative availability of
438 iron oxide through time (Figure 6). The highly reactive iron fraction (FeHR) includes
439 oxide phases (e.g., hematite, magnetite) and reduced phases (e.g., pyrite and iron
440 carbonate minerals) (Raiswell and Canfield, 1998) and thus can be used to assess the
441 original iron oxide content (before and after reduction) of marine sediments (see below).

442 Despite changes in the oxidation state of Earth's surface, broadly expressed as an
443 increase in atmospheric and oceanic oxygen through time, the availability of FeHR in
444 marine shale appears relatively static (Figure 6). Indeed, Sperling et al. (2015) find
445 similarly unchanged iron speciation from the Proterozoic to the early Paleozoic. Iron data
446 have also been screened to exclude samples with FeHR/FeT values greater than 0.38 (the
447 threshold for sediments deposited under anoxic conditions; Poulton and Raiswell, 2002),
448 to remove samples with elevated FeHR that are unrelated to sedimentary Fe³⁺ delivery.
449 This restricted data set likewise does not show significant variability among the time
450 intervals of interest here. However, iron speciation data are not equally available for the
451 different time periods (Sperling et al., 2015). More continuous population of this data set
452 may reveal temporal variability that is missed by this compilation.

453

454 4.3.3 Aqueous Sulfate

455 The understanding of the temporal evolution of marine sulfate concentrations has
456 developed significantly over the past twenty years. This understanding stems from fluid
457 inclusion data (Horita et al., 2002; Lowenstein et al., 2003), sulfur isotope variability

458 (Algeo et al., 2015; Gill et al., 2011; Kah et al., 2004; LaFlamme et al., 2021; Planavsky
459 et al., 2012) and fractionation magnitude experiments (Habicht et al., 2002), modeling
460 (Berner, 2004; Fakhraee et al., 2018; Fakhraee et al., 2019; Krause et al., 2022; Shi et al.,
461 2022) and the occurrence of marine evaporite deposits in the geologic record (Evans,
462 2006; Halevy et al., 2012; Wortmann and Chernyavsky, 2007). Sulfate concentrations
463 (Figure 7) exhibit a transient rise in association with the ~2.3 to 2.1 Ga Lomagundi
464 interval (Planavsky et al., 2012; Salop, 1982; Schröder et al., 2008) which overlaps with
465 the beginning of the relatively concretion-abundant interval at ~2.15 to 1.75 Ga
466 (Melezhik and Fallick, 1996). Evaporite paragenetic data that show halite saturation prior
467 to gypsum/anhydrite may indicate a return to low sulfate concentrations by ~1.9 Ga
468 (Blättler et al., 2018; Pope and Grotzinger, 2003).

469 At ~1.7 Ga sulfate concentrations have been estimated at ~1.5 mM and remain
470 below ~5 mM until ~750 Ma where sulfate concentrations increase to $\sim 10 \pm 5$ mM
471 (Blättler et al., 2020; Kah et al., 2004; Krause et al., 2022), similar to the Phanerozoic
472 minimum (Horita et al., 2002; Lowenstein et al., 2003). Within the Phanerozoic, sulfate
473 concentrations vary (Figure 7b), reaching up to ~28 mM in the modern (Horita et al.,
474 2002; Lowenstein et al., 2003). This variability is broadly characterized by two stepwise
475 increases, one occurring across the Ediacaran–Cambrian boundary where concentrations
476 are thought to have reached up to ~10 mM in the early Cambrian and the other beginning
477 in the late Paleozoic. The timing of late Paleozoic sulfate increase varies depending on
478 literature source; however most reconstructions display an increase at the beginning or
479 within the Carboniferous. Note that the sulfate records presented in Figure 7 may not
480 include brief episodes of sulfate fluctuation such as those associated with the Permian–

481 Triassic interval (Luo et al., 2010; Song et al., 2014) and Cretaceous Ocean Anoxic
482 Events (Adams et al., 2010; Ohkouchi et al., 1999).

483

484 **4.4. Evolving carbon isotope distribution in shallow diagenetic environments** 485 **throughout Earth history**

486 As discussed above, $\Delta^{13}\text{C}_{\text{con-sw}}$ provides insights into temporal changes in shallow
487 marine diagenesis, particularly when isotope compositions exceed or fall below threshold
488 values. Data mean, maximum, minimum and range values for different age intervals
489 demonstrate significant temporal variability (Figure 4), perhaps related to evolving
490 marine diagenetic environments. It is important to note that the data-limited
491 Neoproterozoic and older record may be more susceptible to biases associated with local
492 rather than global environmental controls (depositional environment, etc.) compared to
493 the data-replete younger record. We acknowledge that additional data collection may help
494 resolve this potential bias and interpret the concretion carbon isotope variability
495 demonstrated here in the context of broad temporal changes in Earth's surface
496 environment. A lack of clear changes in reactive/oxide iron phases (Figure 6,
497 Supplementary Figure 6) suggests that particulate iron oxides do not drive $\Delta^{13}\text{C}_{\text{con-sw}}$
498 variability. Thus, concretion isotope evolution is discussed in the context of other
499 potential controls in the following discussion.

500 Prior to ~2.15 Ga, concretions yield values that overlap with or exceed
501 contemporaneous seawater values (i.e., $\Delta^{13}\text{C}_{\text{con-sw}} \geq 0\%$, Figure 3). The earliest
502 concretions (~2.8 Ga) express positive $\Delta^{13}\text{C}_{\text{con-sw}}$ values indicating formation as a result
503 of methanogenesis (Dix et al., 1995). Molecular clock studies suggest early evolution of

504 methanogenesis metabolisms, perhaps originating at ~3.8 to 4.1 Ga (Supplementary
505 Figure 5) (Battistuzzi et al., 2004), well before the formation of these earliest known
506 concretions. Later Archean concretions within ~2.6 Ga rocks express $\delta^{13}\text{C}$ values that do
507 not differ significantly from seawater values (Figure 3a), suggesting a dominantly marine
508 DIC or primary carbonate mineral dissolution source.

509 The prevalence of near neutral $\Delta^{13}\text{C}_{\text{con-sw}}$ values during the Precambrian (Figure
510 3) may reflect the combined effects of low sulfate availability and high marine DIC
511 contents. As confirmed by model results, lower sulfate concentrations limit porewater
512 oxidation of sedimentary organic matter and methane and preclude severe decreases in
513 $\delta^{13}\text{C}_{\text{DIC}}$ (Figure 8 and Supplementary Figure 7) and thus $\Delta^{13}\text{C}_{\text{con-sw}}$. This is consistent
514 with previous modelling work exploring impacts of low sulfate concentration on
515 porewater and authigenic carbonate $\delta^{13}\text{C}$ (Laakso and Schrag, 2020). Marine DIC
516 contents may have been relatively high early in Earth history as supported by muted
517 variability in marine $\delta^{13}\text{C}$ (Bartley and Kah, 2004) and carbonate fabrics that indicate
518 rapid precipitation (Grotzinger and James, 2000). Under elevated marine DIC conditions,
519 shallow porewaters would be buffered against isotope modification by diagenesis. The
520 potential impacts of an increased marine DIC reservoir are demonstrated in Figure 9.
521 Importantly, under low sulfate and high marine DIC conditions, porewater $\delta^{13}\text{C}_{\text{DIC}}$
522 variability is diminished, manifested primarily as an increase in minimum values. Under
523 higher sulfate concentrations, the impacts of increasing marine DIC are less substantial.
524 Therefore, high marine DIC values during the Precambrian may have contributed to the
525 limited variability observed in $\Delta^{13}\text{C}_{\text{con-sw}}$.

526 Conclusively oxidation-derived carbonate concretions first appear at ~2.15 Ga. In
527 fact, all concretion-hosting units between ~2.15 and 1.75 Ga include samples with
528 predominantly negative $\Delta^{13}\text{C}_{\text{con-sw}}$ (Figure 3a). The $\Delta^{13}\text{C}_{\text{con-sw}}$ values extend down to ~ -
529 25‰, consistent with at least partial carbon incorporation from organic matter, methane
530 or both (Melezhik and Fallick, 1996). The $\Delta^{13}\text{C}_{\text{con-sw}}$ value of Lomagundi concretions
531 (and other Precambrian-aged concretions) is constrained by nearby limestones considered
532 to reflect primary marine DIC (see Results). In this regard, the ^{13}C -depleted $\Delta^{13}\text{C}_{\text{con-sw}}$
533 values of the Lomagundi interval should not be impacted by potential facies dependency
534 of primary $\delta^{13}\text{C}$ values (Prave et al., 2022). In addition, the limestone $\delta^{13}\text{C}$ values used to
535 constrain $\Delta^{13}\text{C}_{\text{con-sw}}$ do not exceed +5.4‰ (Supplementary Table 1) and thus do not drive
536 the low $\Delta^{13}\text{C}_{\text{con-sw}}$ during this interval.

537 Intriguingly, the Lomagundi interval post-dates the GOE and coincides with a
538 transient increase in marine sulfate concentration (Planavsky et al., 2012). Concretions of
539 the Lomagundi interval express $\Delta^{13}\text{C}_{\text{con-sw}}$ values significantly lower than the preceding
540 and following Precambrian (Figure 5), perhaps testament to a significant control of
541 increased marine sulfate on porewater DIC (see Figure 8a). Concretions with the lowest
542 $\Delta^{13}\text{C}_{\text{con-sw}}$ values formed during the highest marine sulfate concentrations (up to ~ 11
543 mM, Fakhraee et al., 2019; Planavsky et al., 2012) of the Lomagundi interval (Figure 7a).
544 Thereafter, values increase but remain negative until ~1.75 Ga, despite an apparent
545 massive drawdown in marine sulfate at the tail end of the Lomagundi event (Planavsky et
546 al., 2012). Unfortunately, marine sulfate concentrations are not well resolved between the
547 sulfate “crash” and ~1.75 Ga. Constraining sulfate concentrations in this interval would
548 provide additional insight.

549 The next occurrence of carbonate concretions is reported in the ~1.4 Ga
550 Xiamaling Formation. These concretions express $\Delta^{13}\text{C}_{\text{con-sw}}$ near 0‰, interpreted to
551 represent a marine DIC carbon source (Liu et al., 2019) rather than one that requires
552 oxidative processes. Sulfate concentrations were relatively low at 1.4 Ga (Figure 7),
553 perhaps explaining the return to near neutral $\Delta^{13}\text{C}_{\text{con-sw}}$. The next youngest reported
554 concretions occur in shales of the ~745 Ma Kwagunt Formation of the Chuar Group
555 (Dehler et al., 2005). These concretions exhibit $\Delta^{13}\text{C}_{\text{con-sw}}$ values ranging from ~ -15 to ~
556 -7‰ (supplemented with new data reported here) and a return to at least partial carbon
557 derivation from the oxidation of organic matter and/or methane. Intriguingly, sulfate
558 concentrations may have been relatively high during this time interval (Kah et al., 2004),
559 which was followed by subsequent decreases associated with Neoproterozoic glacial
560 intervals (Hurtgen et al., 2002). Thus prior to the Cambrian, low $\Delta^{13}\text{C}_{\text{con-sw}}$ values
561 coincide with intervals of transient high marine sulfate concentrations.

562 Negative $\Delta^{13}\text{C}_{\text{con-sw}}$ values dominate the relatively well-resolved Phanerozoic
563 record thereafter (Figure 3), when marine sulfate concentrations were high. Indeed, mean
564 $\Delta^{13}\text{C}_{\text{con-sw}}$ values are significantly lower in the Phanerozoic compared to non-Lomagundi
565 Precambrian counterparts (Figure 4a). Phanerozoic mean $\Delta^{13}\text{C}_{\text{con-sw}}$ values range from ~ -
566 7.9 to -5.6‰ whereas the non-Lomagundi Precambrian mean $\Delta^{13}\text{C}_{\text{con-sw}}$ value is ~ -0.5‰
567 (Figure 4). This decrease demonstrates the oxidative impact of a growing marine sulfate
568 reservoir. Intriguingly, the mean $\Delta^{13}\text{C}_{\text{con-sw}}$ value remains relatively stable throughout the
569 Phanerozoic, despite a subsequent increase in marine sulfate during the mid- to late
570 Paleozoic. The static Phanerozoic mean $\Delta^{13}\text{C}_{\text{con-sw}}$ values developed, in part, as a result of
571 the expansion of the concretion carbon isotope record to include compositions both

572 depleted and enriched in ^{13}C (Figure 4). The implications of this expansion as related to
573 changing minimum and maximum $\Delta^{13}\text{C}_{\text{con-sw}}$ are discussed below.

574 Early Paleozoic concretions (Cambrian to Devonian samples) express a minimum
575 $\Delta^{13}\text{C}_{\text{con-sw}}$ value that extends down to $\sim -25\text{‰}$, the approximate concurrent organic matter
576 composition. This minimum value is similar to that of the Lomagundi interval (Figure 4,
577 Supplementary Table 5). Reported marine sulfate concentrations are comparable for these
578 two time intervals, reaching up to ~ 10 mM (Figure 7). This similarity underscores the
579 control of marine sulfate concentrations on $\Delta^{13}\text{C}_{\text{con-sw}}$.

580 $\Delta^{13}\text{C}_{\text{con-sw}}$ values do not drop below -25‰ until ~ 325 Ma (Figures 3 and 4),
581 following reported elevated marine sulfate concentrations in the Carboniferous (Bernier,
582 2004; Gill et al., 2007; Halevy et al., 2010) and representing the first conclusive evidence
583 for methane oxidation-derived inorganic carbon. Similar low isotope compositions persist
584 throughout the remaining record (see minimum $\Delta^{13}\text{C}_{\text{con-sw}}$ values in Figure 4). These data
585 imply that the AOM pathway has been an important methane consumption and
586 concretion producing reaction since at least ~ 325 Ma and perhaps earlier (methane
587 oxidation-derived concretions need not produce values below -25‰ if other carbon
588 sources also contributed). Modern marine sediments often show porewater $\delta^{13}\text{C}_{\text{DIC}}$
589 minima that approach but do not drop below the organic matter value despite active
590 AOM, suggesting quantitative oxidation of locally produced methane by sulfate in
591 shallower sediments (Meister et al., 2019). Modeling results indicate that both high
592 marine sulfate and an external source of methane are required to produce isotope
593 compositions significantly lower than -25‰ (Figure 8 and Supplementary Figure 7). The
594 degree of ^{13}C depletion below -25‰ ultimately depends on marine sulfate content, the

595 amount of methane entering the system and its $\delta^{13}\text{C}$. Perhaps not surprisingly, non-
596 concretionary methane cold-seep authigenic carbonates express similarly diagnostic, low
597 $\delta^{13}\text{C}$ values at about the same time. The transition to conclusively methane-oxidation-
598 derived seep carbonates has likewise been attributed to increased marine sulfate
599 concentrations (Bristow and Grotzinger, 2013). The Paleozoic appearance of
600 diagnostically low concretion and seep-carbonate $\Delta^{13}\text{C}_{\text{con-sw}}$ values did not result from the
601 concurrent evolution of organisms capable of AOM as these lineages are relatively
602 ancient, perhaps existing since ~2.6 to 2.8 Ga (Supplementary Figure 5) (Battistuzzi et
603 al., 2004; Hinrichs, 2002).

604 The relationship of AOM-derived authigenic carbonate to temporal delivery of
605 external methane is more difficult to resolve. We speculate that the generation of
606 significant methane accumulations may in part be related to enhanced organic carbon
607 burial in the Phanerozoic (from marine and/or terrestrial sources, see above). This
608 methane could then be delivered to shallow sediments relatively quickly (perhaps through
609 methane hydrate dissolution, for example) and oxidized to generate the severe ^{13}C
610 depletions diagnostic of AOM. A negative correlation between mean organic carbon
611 burial rates and minimum $\Delta^{13}\text{C}_{\text{con-sw}}$ values (that also drop below -25% , Figure 10)
612 supports this assertion. Constraining the temporal distribution of large methane reserves
613 is beyond the scope of this work, but may provide additional insight.

614

615 **4.5. Identifying dominant controls on carbon isotope minima and maxima of** 616 **inorganic carbon**

617

618 *4.5.1. $\delta^{13}\text{C}$ minima in the AOM zone*

619 As discussed above, sulfate appears to play an integral role in governing Earth's
620 shallow marine diagenetic environments. The relationship between marine sulfate
621 concentration and concretion isotope compositions is emphasized in Figure 8d. This plot
622 demonstrates a strong negative correlation between the sulfate content and minimum
623 $\Delta^{13}\text{C}_{\text{con-sw}}$ during the time intervals discussed above. Encouragingly, this correlation
624 mimics the porewater minimum $\delta^{13}\text{C}_{\text{DIC}}$ model results of Figure 8c where the impacts of
625 changing marine sulfate contents are displayed under variable external methane flux.
626 Ultimately these results demonstrate that marine sulfate concentrations and the delivery
627 of external methane dictate the minimum $\delta^{13}\text{C}_{\text{DIC}}$ (and $\Delta^{13}\text{C}_{\text{con-sw}}$) values generated in the
628 AOM zone.

629

630 *4.5.2. $\delta^{13}\text{C}$ maxima in the methanogenic zone*

631 Collectively, Phanerozoic concretions express $\Delta^{13}\text{C}_{\text{con-sw}}$ values that are consistent
632 with oxidation and methane-producing reactions. The increase in the range in isotope
633 compositions within the Phanerozoic is manifested as both a decrease in minimum and an
634 increase in maximum values (Figures 3 and 4). As discussed above, sulfate appears to be
635 an important external oxidant as revealed by relationships between sulfate concentration
636 and $\Delta^{13}\text{C}_{\text{con-sw}}$ data. However, the coincident increase in the abundance of conclusively
637 methanogenesis-derived concretions (as indicated by positive $\Delta^{13}\text{C}_{\text{con-sw}}$) is not
638 straightforwardly attributable to increasing sulfate concentrations.

639 It has been proposed that an increase in the quantity of organic matter delivered to
640 the sediment-water interface may dictate the relative importance of concretion-yielding

641 diagenetic reactions, such that higher amounts promote organic matter persistence to the
642 deeper methanogenesis zone (Mozley and Burns, 1993). In this regard, the increase in the
643 quantity of organic matter in Phanerozoic compared to Neoproterozoic marine sediments
644 recognized by Sperling and Stockey (2018) and supported by model reconstructions
645 (Krause et al., 2022; Krissansen - Totton et al., 2021; Planavsky et al., 2022) may have
646 promoted the expansion of methanogenesis (Sivan et al., 2007). However, maximum
647 $\Delta^{13}\text{C}_{\text{con-sw}}$ values do not show significant correlation with organic carbon burial (Figure
648 11a). Figure 11b and Supplementary Figure 8 show variability in modeled maximum
649 $\delta^{13}\text{C}_{\text{DIC}}$ values as a function of TOC deposited at the seafloor. Note that the global
650 organic carbon burial rate does not dictate the specific quantity of TOC deposited on the
651 seafloor at any given location. However, broad increases in organic carbon burial are
652 likely to lead to generally higher TOC delivery globally, explaining the motivation
653 behind panel comparisons in Figure 11. As initial TOC increases so does the maximum
654 $\delta^{13}\text{C}_{\text{DIC}}$; however isotope compositions do not exceed $\sim +15\text{‰}$ (Figure 12b,
655 Supplementary Figure 8). Meister et al. (2019) demonstrate this maximum threshold
656 under modern marine sulfate concentrations (28 mM) and new model results show that
657 lower sulfate concentrations do not significantly increase $\delta^{13}\text{C}_{\text{DIC}}$ maximum values. Thus
658 the $\Delta^{13}\text{C}_{\text{con-sw}}$ values above $\sim +20\text{‰}$ commonly expressed in the Phanerozoic record
659 cannot be accounted for by organic carbon burial alone.

660 It has been demonstrated that increased sedimentation rates lead to faster organic
661 matter burial and degradation in the deeper methanogenesis zone (Burns and Baker,
662 1987; Pisciotto and Mahoney, 1981; Scotchman, 1991), largely due to limitations

663 associated with sulfate diffusion from the overlying water column. As yet, no data have
664 been reported that indicate an increased sedimentation rate in the Phanerozoic
665 compared to earlier times. Organic matter reactivity can also impact degradation
666 mechanisms. Similar to increased sedimentation rate, less reactive organic matter
667 degrades more slowly and can persist to deeper sediment depths to experience
668 preferential degradation in the methanogenesis zone (Meister et al., 2019). Thus, higher
669 proportions of more refractory organic matter can cause porewater DIC to become more
670 ^{13}C -enriched with depth. The evolution of organic matter reactivity is not well known,
671 but the arrival and diversification of terrestrial plants may have prompted the delivery of
672 less reactive organic material (Aller et al., 1996; Burdige, 2005; Hedges et al., 1997) to
673 marginal environments since the Silurian (Kenrick and Crane, 1997; Raiswell and
674 Berner, 1986). Maximum $\Delta^{13}\text{C}_{\text{con-sw}}$ values, however, show an increase well before the
675 appearance of land plants (Supplementary Figure 5). Furthermore, significant decreases
676 in organic matter degradation rate are unable to account for porewater DIC ^{13}C
677 enrichments above $\sim +10\text{‰}$ in the methanogenesis zone (Meister et al., 2019) like those
678 expressed in the concretion record. Whereas sedimentation rate and organic matter
679 quantity and reactivity may impact organic matter degradation mechanisms, these factors
680 alone cannot explain the observed data.

681 Another more speculative explanation involves an increase in the magnitude of
682 carbon isotope fractionation during methanogenesis. Fractionation factors between
683 methane and DIC ($\alpha_{\text{methane-DIC}}$) determined from culture and modern porewater data are
684 between 0.95 and 1.0 (Londry et al., 2008; Whiticar et al., 1986). Some modern marine
685 sediments, however, express $\delta^{13}\text{C}_{\text{DIC}}$ maxima that are difficult to reconcile with low

686 fractionation magnitudes (Meister et al., 2019). In addition, the concretion record
687 suggests that higher maximum porewater $\delta^{13}\text{C}_{\text{DIC}}$ compositions occurred in more recent
688 marine sediments, exceeding the values that can be reached by using the experimentally
689 determined fractionation factors mentioned above. It has been suggested that substrate
690 limitation during AOM promotes reaction reversibility as part of the Wood-Ljungdahl
691 pathway and that this reversibility can lead to isotopic fractionation that approaches
692 theoretical equilibrium magnitudes (Yoshinaga et al., 2014). Similar reversibility may
693 affect isotope fractionation during methanogenesis as suggested by some culture
694 experiments conducted under substrate limited conditions (Botz et al., 1996 ; see
695 comparison in Meister and Reyes (2019)) and isotope separations between co-occurring
696 porewater DIC and methane recognized in porewaters of many marine sediments
697 (e.g.,(Galimov and Kvenvolden, 1983; Heuer et al., 2009; Meister et al., 2019; Paull et
698 al., 2000; Pohlman et al., 2008) . It is conceivable that under extreme substrate limitation
699 (which is common in sub-seafloor environments) the fractionation factor may approach
700 the theoretical low-temperature equilibrium value ($\alpha_{\text{methane-DIC}} = 0.93$,(Bottinga, 1969);
701 Horita (2001)).

702 To explore the effect of the fractionation factor on maximum $\delta^{13}\text{C}_{\text{DIC}}$, model
703 experiments were conducted at variable $\alpha_{\text{methane-DIC}}$ (from 0.92 to 0.98, Supplementary
704 Figures 9 and 10). In these experiments, methane was sourced entirely from within the
705 model domain (i.e., no external methane flux imposed). Maximum $\delta^{13}\text{C}_{\text{DIC}}$ values
706 increased at lower fractionation factors, reaching up to $\sim +9\text{‰}$ (at $\alpha_{\text{methane-DIC}} = 0.92$).
707 However, in this most extreme scenario the isotopic separation between methane and
708 DIC becomes very high ($\sim 100\text{‰}$) and exceeds differences commonly observed in

709 measured profiles. Increasing the external methane flux did not significantly change
710 maximum $\delta^{13}\text{C}_{\text{DIC}}$ when external methane was assigned the $\delta^{13}\text{C}$ composition of the in-
711 situ methane produced at the bottom of the model domain (Supplementary Figures 9 and
712 10). Thus, increased isotope fractionation alone cannot account for the highly positive
713 $\Delta^{13}\text{C}_{\text{con-sw}}$ values expressed in the concretion record.

714 One mechanism that could promote extreme ^{13}C enrichment of porewater DIC
715 involves equilibration with externally derived methane exhibiting a relatively high $\delta^{13}\text{C}$.
716 Such methane can form through thermogenic processes and exhibit isotope compositions
717 near $\sim -40\%$. Hypothetically, equilibration between thermogenic methane and DIC could
718 result in $\delta^{13}\text{C}_{\text{DIC}}$ values up to $\sim +30$ to $+40\%$ if the methanogenic reaction is reversible
719 (such that isotope exchange occurs between methane and DIC) and an isotope offset of
720 ~ 70 to 80% is maintained. Such a process may in part explain the very high $\delta^{13}\text{C}_{\text{DIC}}$
721 values recognized at some Cascadia Margin sites (Heuer et al., 2009), although other
722 factors including gas escape to the water column may also play a role (Birgel et al., 2015;
723 Meister et al., 2019). Despite the poorly understood complexities involved in isotope
724 fractionation during methanogenesis and the potential role of equilibration, the
725 mechanisms of ^{13}C enrichments and depletions in porewater DIC may both involve the
726 influx of external methane. As argued above, methane formation (thermogenic or
727 biogenic) may have been stimulated as a result of enhanced organic carbon burial during
728 the Phanerozoic, thus providing a singular driver for the roughly contemporaneous
729 expansion in $\Delta^{13}\text{C}_{\text{con-sw}}$ range.

730

731 **4.6. Implications for the $\delta^{13}\text{C}$ of authigenic carbonate**

732 Modern authigenic carbonates form within marine sediments as a result of similar
733 reactions to those proposed for carbonate concretions. In fact, carbonate concretions are
734 thought to represent ancient analogs to modern authigenic carbonates (Loyd and
735 Berelson, 2016). This connection has been confounded in part as a result of the inability
736 to identify core-recovered carbonate as concretionary in nature (core sampling limits the
737 ability to characterize the three-dimensional structure of large objects). The similarity
738 between the carbon isotope composition of authigenic carbonate ($\delta^{13}\text{C}_{\text{auth}}$) and Triassic to
739 Holocene $\Delta^{13}\text{C}_{\text{con-sw}}$ values (Figure 4) provides further support to the proposed analogy.
740 Thus, the concretion-based record presented here may provide insight into the evolution
741 of $\delta^{13}\text{C}_{\text{auth}}$ through time.

742 As with the carbon isotope composition of carbonate concretions, $\delta^{13}\text{C}_{\text{auth}}$ is likely
743 to have changed as a result of broad changes in the oxidation state of marine bottom
744 waters. Previous work aimed at exploring the impact of authigenic carbonate
745 precipitation on global carbon budgets and marine $\delta^{13}\text{C}_{\text{DIC}}$ hinges intimately on
746 constraining an average $\delta^{13}\text{C}_{\text{auth}}$ value (Schrag et al., 2013). Indeed, Schrag et al. (2013)
747 and Laakso and Schrag (2020) propose that average $\delta^{13}\text{C}_{\text{auth}}$ values may have been
748 different in the past and this inference is supported by the Precambrian $\Delta^{13}\text{C}_{\text{con-sw}}$ record.
749 When data outside the Lomagundi interval are considered, mean Precambrian $\Delta^{13}\text{C}_{\text{con-sw}}$
750 values differ significantly from other time intervals (Figure 4). The average Precambrian
751 non-Lomagundi $\Delta^{13}\text{C}_{\text{con-sw}}$ value is very near neutral ($\sim -0.5\text{‰}$) and indistinguishable
752 from contemporaneous primary carbonate. Therefore, according to this concretion data
753 set, burial of Precambrian authigenic carbonate would have had little impact on marine
754 $\delta^{13}\text{C}$ variability. Once marine sulfate concentrations exceeded ~ 5 mM (during brief

755 transient intervals in the Precambrian or otherwise), mean $\Delta^{13}\text{C}_{\text{con-sw}}$ values consistently
756 lie between ~ -10 and $\sim -5\%$. These compositions agree with recent findings of Laakso
757 and Schrag (2020), are comparable to, to somewhat higher than approximate $\delta^{13}\text{C}_{\text{auth}}$
758 values proposed by Schrag et al. (2013), and considerably higher than the estimated
759 modern average $\delta^{13}\text{C}_{\text{auth}}$ value of $-20.5 \pm 3.5\%$, based on compiled pore water
760 geochemical data (Bradbury and Turchyn, 2019). Differences in mean values may in part
761 be explained by the exclusion of non-concretionary, seafloor methane seep carbonates
762 and/or preferential retention of methanogenesis-formed carbonate in the sampled
763 concretion record.

764

765 **5. CONCLUSIONS**

766 Carbonate concretions primarily occur in Phanerozoic rock units and a
767 concretion-rich interval between ~ 2.15 and 1.75 Ga that overlaps with the enigmatic
768 Lomagundi carbon isotope excursion (Melezhik and Fallick, 1996). This distribution may
769 result from preferential formation during these time intervals, but correlation with the
770 abundance of preserved sedimentary rock precludes identification of an environmental
771 signal in the concretion occurrence record. In contrast, the concretion isotope record
772 provides important information about shallow marine diagenetic environments. Negative
773 $\Delta^{13}\text{C}_{\text{con-sw}}$ values dominate the Phanerozoic and Lomagundi interval and correlate with
774 periods exhibiting high marine dissolved sulfate concentrations and organic carbon burial
775 rates. Concretions with conclusively AOM carbon isotope signals appear at ~ 325 Ma and
776 are relatively common in the younger record, likely in response to a Paleozoic rise in
777 marine sulfate concentrations and significant delivery of external methane. The

778 Phanerozoic record also shows an increase in $\Delta^{13}\text{C}_{\text{con-sw}}$ through time perhaps resulting
779 from increased input of thermogenic methane and isotopic equilibration with porewater
780 DIC. Ultimately, the concretion record demonstrates coeval evolution of Earth's primary
781 marine and shallow diagenetic environments, in part related to shifting redox conditions.

782
783

784 **Acknowledgements**

785 We thank Julie Unson and Miguel Rincon for analytical assistance and Mary Droser for
786 providing Chuar Group samples. Jon Husson provided integral rock abundance data from
787 the Macrostrat database. Insightful communications with Peter Mozley, Doug LaRowe,
788 Kristen Bergmann, Eric Sperling, Maggie Osborn and David Ware and early reviews
789 provided by Ben Gill, Leanne Hancock and one anonymous reviewer were highly
790 beneficial to this manuscript.

1268 (2022).

1269
1270

1271 Figure 8: Porewater model results demonstrating potential controls on $\delta^{13}\text{C}_{\text{DIC}}$ and
1272 comparison to concretion record. Solid and dashed gray lines in a-c represent marine DIC
1273 and organic matter $\delta^{13}\text{C}$, respectively. a) impact of marine sulfate content. Note that as
1274 sulfate concentrations increase, both $\delta^{13}\text{C}_{\text{DIC}}$ minimum and maximum values decrease. b)
1275 impact of external methane flux under modern marine sulfate concentrations. External
1276 methane $\delta^{13}\text{C}$ values are assigned the value achieved at the base of the modeled domain,
1277 deviations from this value impact the minimum $\delta^{13}\text{C}_{\text{DIC}}$. Note that as external methane
1278 input increases, $\delta^{13}\text{C}_{\text{DIC}}$ minimum values decrease and yield compositions below the

1279 organic matter $\delta^{13}\text{C}$ value. c) impact of marine sulfate content under variable external
1280 methane flux (ext. CH_4 flux). Increased sulfate contents yield decreased $\delta^{13}\text{C}_{\text{DIC}}$
1281 minimum and maximum values similar to overall trends observed in a. Note that $\delta^{13}\text{C}_{\text{DIC}}$
1282 depletions produce minimum values that drop well below the organic matter $\delta^{13}\text{C}$ value
1283 under high sulfate conditions. Maximum data trends overlap. In a-c, $\alpha_{\text{methane-DIC}} = 0.94$
1284 and the isotopic difference between methane and DIC was maintained at $\sim 75\%$. d)
1285 comparison between marine sulfate concentrations and minimum $\Delta^{13}\text{C}_{\text{con-sw}}$ for the age
1286 groupings discussed in the text. Blue bands represent ranges from Fakhraee et al., 2018,
1287 2019, all other data are sulfate concentration averages. Notice decrease in minimum
1288 isotope compositions with increasing sulfate content, similar to minimum model data in
1289 c. Linear regressions and correlation strengths also provided.

1290

1291

1292 Figure 9: Modeled variability in $\delta^{13}\text{C}_{\text{DIC}}$ as a function of marine DIC content across a
1293 range of marine sulfate concentrations. Increasing marine DIC yields higher $\delta^{13}\text{C}_{\text{DIC}}$
1294 minima except under the 0 mM sulfate condition. This increase is more pronounced at
1295 lower marine sulfate concentrations. The $\delta^{13}\text{C}_{\text{DIC}}$ maxima are relatively invariant.

1296

1297

1298 Figure 10: Comparison between organic carbon burial and minimum $\Delta^{13}\text{C}_{\text{con-sw}}$ for the
1299 age groupings discussed in the text.

1300

1301 Figure 11: Impacts of organic carbon burial on isotope compositions. a) Comparison
1302 between organic carbon burial and maximum $\Delta^{13}\text{C}_{\text{con-sw}}$ for the age groupings discussed
1303 in the text. b) Modeled variability in $\delta^{13}\text{C}_{\text{DIC}}$ as a function of total organic carbon (TOC)

1304 deposited at the sediment water interface. As TOC contents increase $\delta^{13}\text{C}_{\text{DIC}}$ maximum

1305 values increase, but do not exceed $\sim +15\%$.

47 **Abstract**

48 Early diagenesis of marine organic matter dramatically impacts Earth's surface
49 chemistry by changing the burial potential of carbon and promoting the formation of
50 authigenic mineral phases including carbonate concretions. Marine sediment-hosted
51 carbonate concretions tend to form as a result of microbial anaerobic diagenetic reactions
52 that degrade organic matter and methane, some of which require an external oxidant.
53 Thus, temporal changes in the oxidation state of Earth's oceans may impart a first-order
54 control on concretion authigenesis mechanisms through time. Statistically significant
55 variability in concretion carbonate carbon isotope compositions indicates changes in
56 shallow marine sediment diagenesis associated with Earth's evolving redox landscape.
57 This variability manifests itself as an expansion in carbon isotope composition range
58 broadly characterized by an increase in maximum and decrease in minimum isotope
59 values through time. Reaction transport modelling helps to constrain the potential impacts
60 of shifting redox chemistry and highlights the importance of organic carbon delivery to
61 the seafloor, marine sulfate concentrations, methane production and external methane
62 influx. The first appearance of conclusively anaerobic oxidation of methane-derived
63 concretions occurs in the Carboniferous and coincides with a Paleozoic rise in marine
64 sulfate. The muted variability recognized in older concretions (and in particular for
65 Precambrian concretions) likely reflects impacts of a smaller marine sulfate reservoir and
66 perhaps elevated marine dissolved inorganic carbon concentrations. Causes of the
67 increase in carbon isotope maximum values through time are more confounding, but may
68 be related to isotopic equilibration of dissolved inorganic carbon with externally derived
69 methane. Ultimately the concretion isotope record in part reflects changes in organic

70 matter availability and marine oxidation state, highlighting connections with the
71 subsurface biosphere and diagenesis throughout geologic time.

72

73 **1. INTRODUCTION**

74 Carbonate concretions are isolated zones of relatively high cement content in sediments
75 and sedimentary rocks (Coleman, 1993). These precipitates can exhibit textural and
76 compositional characteristics that indicate initial formation within shallow sediments.
77 Shallow formation indicators include deflection of external lamination (Raiswell, 1971),
78 preservation of delicate primary sedimentary features (such as thin walled shells and
79 macrofauna carcasses) (Allison and Pye, 1994; Blome and Albert, 1985; Bramlette, 1946;
80 El Albani et al., 2001; Heimhofer et al., 2017; Martill, 1988), evidence of biological
81 interaction by burrowing organisms (Bjørlykke, 1973; Hesselbo and Palmer, 1992;
82 Savrda and Bottjer, 1988), erosional exhumation (Hesselbo and Palmer, 1992) and low
83 proxy-based formation temperatures (Dale et al., 2014; Loyd et al., 2012). Therefore,
84 carbonate concretions can result (at least initially) from relatively shallow diagenetic
85 processes that are intimately related to the chemical composition of marine bottom waters
86 and the availability of organic matter delivered to the sediment-water interface. The
87 geochemistry of Earth's marine environments has experienced significant temporal
88 variability in part associated with an overall increase in oxidation state (Lyons et al.,
89 2014), associated fluctuations in marine chemistry (Canfield, 1998) and changes in
90 organic carbon export (Krause et al., 2022; Krissansen - Totton et al., 2021; Planavsky et
91 al., 2022) and organic matter composition (Brocks et al., 2017). In particular, variable

92 organic carbon delivery to the seafloor and marine oxidant abundances (see below) likely
93 impacted shallow diagenetic processes related to remineralization.

94 Marine sediment-hosted carbonate concretions seem to form in association with
95 reactions that involve the microbial degradation of particulate organic matter and/or
96 methane (Irwin et al., 1977). Of these reactions, those considered most important for
97 concretion formation are iron reduction, organotrophic sulfate reduction, methanogenesis
98 and the anaerobic oxidation of methane (AOM) (Claypool and Kaplan, 1974; Coleman,
99 1993; Irwin et al., 1977; Orphan et al., 2004). The carbon isotope composition of
100 porewater DIC ($\delta^{13}\text{C}_{\text{DIC}}$) is impacted by the relative contributions of these pathways
101 wherein organic matter and methane oxidation reactions cause porewater $^{13}\text{C}_{\text{DIC}}$ depletion
102 and methanogenesis causes porewater $^{13}\text{C}_{\text{DIC}}$ enrichment. The magnitude of isotope
103 enrichments and depletions is dictated by oxidant supply and reduced carbon source
104 (organic matter or methane), among other factors (e.g., Meister et al., 2019). Carbonate
105 concretions inherit the carbon isotope composition of porewater DIC owing to minimal
106 isotope fractionation during carbonate precipitation (Emrich et al., 1970; Ohmoto and
107 Rye, 1979). Thus, concretion carbon isotope compositions and can be used to track
108 carbon-phase reactants (organic matter or methane) and/or reaction pathways of shallow
109 marine diagenetic environments through time.

110 Here, carbonate concretion abundance and carbon isotope data (consisting of both
111 new and previously reported data) are used to characterize ancient marine shallow
112 diagenetic environments. These data are assessed through a transient reaction transport
113 model to explore potential impacts of contemporaneous environmental changes.
114 Ultimately, we show that amplified variability in concretion carbon isotope signatures

115 coincides with proposed increases in organic carbon export and marine sulfate
116 concentrations, implicating these factors as important for diagenetic carbonate
117 mineralization throughout geologic time. Modeling results suggest that external methane
118 inputs are likely required to generate severe ^{13}C depletions in concretionary carbonate.
119 Elevated marine dissolved inorganic carbon (DIC) contents may also play a role by
120 muting porewater isotope variability during much of the Precambrian. In addition, we
121 identify potentially counterintuitive coincident changes in methanogenesis-driven
122 diagenesis during the Phanerozoic.

123

124 **2. METHODS**

125 Marine sediment-hosted carbonate concretion occurrence and carbonate carbon
126 isotope composition ($\delta^{13}\text{C}_{\text{con}}$) data (~5,000 data points from ~170 units) were primarily
127 compiled from published reports. New $\delta^{13}\text{C}_{\text{con}}$ data were collected from select time
128 periods where isotope data have not been reported (see Supplementary Tables 1, 2). Host
129 rock formation name, age, and lithology, and concretion mineralogy, crystallographic
130 habit (for septarian concretions), carbon and oxygen isotope data were also collected
131 (Supplementary Tables 1, 2 and 3), as available. Similar information provided for
132 authigenic carbonates recovered from siliciclastic marine sediments is provided for
133 comparison (Supplementary Table 4). Most new concretion data were generated from
134 powders of slabbed samples using a Dremel® rotary tool fitted with a 3-mm carbide drill
135 bit. Triplicate 5-7 mg splits of concretion powders were dissolved in 10% phosphoric
136 acid in sealed and evacuated exetainer vials. The carbon isotope composition of produced
137 CO_2 was determined using a G2121-i Picarro® Cavity Ringdown Spectrometer (CRDS)

138 via introduction through an Automate® carbonate preparation device. Limited additional
139 new carbon isotope data from the Chuar Group (nine data points) were generated using a
140 VG Instruments PRISM II isotope ratio mass spectrometer after sample dissolution in a
141 common acid bath at 90°C. Isotope compositions reported in the typical delta (δ) notation
142 in permil (‰) versus the VPDB standard. Isotope values were determined by comparison
143 with international [IAEA NBS-18 ($\delta^{13}\text{C} = -5.014\text{‰}$, $\delta^{18}\text{O} = -23.2\text{‰}$), Carrara Marble
144 ($\delta^{13}\text{C} = +2.46\text{‰}$, $\delta^{18}\text{O} = -2.37\text{‰}$), NIST SRM 915B ($\delta^{13}\text{C} = -8.53$)] and laboratory
145 [CRCP90 ($\delta^{13}\text{C} = -4.13\text{‰}$), CRC200 ($\delta^{13}\text{C} = +2.12\text{‰}$), WD-1A ($\delta^{13}\text{C} = -42.61\text{‰}$)]
146 standards. New carbon isotope data reproducibility was better than $\pm 1.0\text{‰}$ (2 s.d.).

147 Statistical parameter estimation of the mean, variance, minimum, maximum and
148 range of carbon isotope data was accomplished via bootstrapping (Efron, 1979) across
149 select time periods (Supplementary Table 5). Biases in estimating extrema were
150 simulated empirically from repeated resampling, and then applied to adjust distributions
151 for parameter estimation of maximum and minimum values (Efron, 1982). Confidence
152 intervals (95%) for each numerical summary across the selected time periods were
153 generated via the bootstrap empirical distributions, as were pairwise statistical hypothesis
154 tests between each pairwise combination of selected time periods.

155 The factors that control potential ranges in carbon isotope compositions were
156 evaluated using a previously described transient reaction transport model (Meister et al.,
157 2013; Meister et al., 2019). This model was developed in part to constrain transport and
158 biogeochemical impacts on isotope compositions of the dominant carbon-containing
159 porewater phases. Marine sulfate concentrations, organic carbon content at the sediment-
160 water interface, external methane delivery, isotope fractionation during methanogenesis

161 and marine DIC contents were varied to explore impacts on porewater DIC isotope
162 compositions. Here, complete ranges in porewater $\delta^{13}\text{C}_{\text{DIC}}$ values (including maxima and
163 minima) are explored without predicting specific depths of carbonate authigenesis (in
164 contrast to Laakso and Schrag (2020)). The modelled porewater isotope compositions are
165 thus reflective of all of the possible concretion isotope compositions, resolving potential
166 uncertainties in mineralization depth (e.g., Meister et al., 2019). Model inputs and
167 parameterizations are provided in the Supplementary Materials (“Modelling Approach”),
168 as is a diagram demonstrating how maximum and minimum values were determined
169 (Supplementary Figure 1). Model results are compared to the ancient concretion carbon
170 isotope record to identify potential drivers of temporal variability, they are not intended
171 to recreate specific intervals of the record.

172

173 **3. RESULTS**

174 Carbonate concretions have been identified in 379 geologic formations. Of these
175 units, carbon isotope data have been compiled or generated from 173, representing ~ 46%
176 $\delta^{13}\text{C}_{\text{con}}$ coverage. The age distribution of carbonate concretions is not uniform; the vast
177 majority have been identified in units younger than 600 Ma (Figure 1). An exception to
178 this broad temporal trend is a relatively short-lived, concretion-abundant interval between
179 ~2150 to 1750 Ma (Figure 2b). Within the Phanerozoic, concretion occurrence generally
180 increases (aside from a few exceptions) up to the modern (Figure 1c). As has been
181 recognized in a previous compilation (Mozley and Burns, 1993) concretions mostly occur
182 within shale hosts (Figure 2a) and calcite represents the dominant mineralogy (Figure
183 2b).

184 Carbon isotope compositions range from -54.0 to $+32.5\text{‰}$ for the entire data set.

185 Absolute $\delta^{13}\text{C}_{\text{con}}$ values provide only limited insight into concretion formation
186 mechanisms. These data must be corrected to account for the contemporaneous seawater
187 $\delta^{13}\text{C}$ value, which represents the starting condition that is subsequently modified
188 by shallow diagenetic processes. This correction is relatively unimportant for Cenozoic
189 concretions because seawater $\delta^{13}\text{C}$ does not significantly deviate from 0‰ . However, a
190 growing body of primary carbonate (i.e., non-diagenetic) carbon isotope data suggests
191 that seawater $\delta^{13}\text{C}$ was significantly different in earlier time periods (in particular during
192 intervals within the Proterozoic), in some cases reaching values as high as $+11$
193 (e.g., Maheshwari et al., 2010) to as low as -12‰ (e.g., Halverson et al., 2005). In order
194 to account for changes in seawater carbon isotope compositions, the quantity $\Delta^{13}\text{C}_{\text{con-sw}}$ is
195 defined as $\Delta^{13}\text{C}_{\text{con-sw}} = \delta^{13}\text{C}_{\text{con}} - \delta^{13}\text{C}_{\text{sw}}$, where $\delta^{13}\text{C}_{\text{sw}}$ is the contemporaneous seawater
196 carbon isotope composition as determined by either 1) the primarily Phanerozoic curve of
197 Veizer et al. (1999) or 2) stratigraphically nearby non-diagenetic carbonate beds. The
198 $\Delta^{13}\text{C}_{\text{con-sw}}$ parameter presented in Figure 4 thus reflects specific diagenetic pathways more
199 directly than $\delta^{13}\text{C}_{\text{con}}$. Uncertainties related to the primary carbonate $\delta^{13}\text{C}$ value and
200 temporal variability in isotope fractionation associated with organic matter production
201 (e.g., isotopic differences between contemporaneous marine DIC and organic carbon
202 varying between ~ 30 and 25‰ , Kump and Arthur, 1999) are accounted for by the gray
203 solid and dashed bands in Figure 3.

204 Values of $\Delta^{13}\text{C}_{\text{con-sw}}$ exhibit significant changes since ~ 2800 Ma (Figure 3), as
205 outlined below.

206

- 207
- Archean concretion samples from ~2800, 2603 and 2600 Ma units yield
- 208 $\Delta^{13}\text{C}_{\text{con-sw}}$ values that range from +9.9 to +15.0‰, -4.5 to +1.8‰ and ± 0.9
- 209 to ± 2.4 ‰, respectively.
- Early Proterozoic concretions (of the ~2150 to 1750 Ma interval discussed
- 210 above) show $\Delta^{13}\text{C}_{\text{con-sw}}$ values that range from -24.5 to +1.4‰. ~1400 Ma
- 211 concretions express $\Delta^{13}\text{C}_{\text{con-sw}}$ from -1.1 to +1.9‰.
- Concretions from a single middle Neoproterozoic site (~745 Ma) exhibit
- 212 $\Delta^{13}\text{C}_{\text{con-sw}}$ values ranging from -15.6 to -7.9‰.
- Late Neoproterozoic (~560 and 555 Ma) carbonate concretions exhibit
- 213 $\Delta^{13}\text{C}_{\text{con-sw}}$ values from -3.5 to +5.4‰.
- Cambrian to Devonian (542-360 Ma) concretions display an increased
- 214 range in $\Delta^{13}\text{C}_{\text{con-sw}}$, with values extending from ~ -25.3‰ to +24.5‰.
- Younger concretions within Carboniferous to Permian sedimentary rocks
- 215 express $\Delta^{13}\text{C}_{\text{con-sw}}$ values extending from -54.6 to +9.5‰.
- Triassic to Holocene concretions yield $\Delta^{13}\text{C}_{\text{con-sw}}$ values ranging from -
- 216 55.7 to +31.5‰.

223

224 For comparison, marine sedimentary authigenic carbonate data (compiled in

225 Supplementary Table 4, after Loyd and Smirnoff (2022)) are also provided. Note that

226 sedimentary authigenic carbonates characterized as “modern”, may rather have formed at

227 any time since the ages of the host sediment (host sediment ages provided in

228 Supplementary Table 4). Similarly, carbonate concretions must have formed after

229 deposition of the host rock. However, given that these precipitates form relatively soon

230 after deposition, concretion ages are here approximated as the same as their host
231 sediment. Means, minima, maxima and ranges are provided for the above age groupings
232 in Figure 4; histograms are displayed in Supplementary Figure 2, and statistical similarity
233 analyses are provided in Supplementary Table 5.

234 As with primary carbonate phases, concretions may be altered by later diagenetic
235 processes that overprint original carbon isotope compositions as often indicated by ^{18}O -
236 depleted compositions (Bojanowski et al., 2014; Gross and Tracey Jr, 1966; Seewald,
237 2003). To screen for potential late diagenetic impacts on the temporal record, plots
238 limited to samples expressing oxygen isotope compositions $> -10\text{‰}$ and $> -5\text{‰}$ have
239 been generated (Supplementary Figure 3). These plots express similar trends as the
240 complete record, suggesting that later diagenetic alteration does not strongly influence the
241 broad temporal trends in $\Delta^{13}\text{C}_{\text{con-sw}}$.

242

243 **4. DISCUSSION**

244 The concretion occurrence and carbon isotope data presented here provide a more
245 detailed picture of a temporal variability hypothesized by previous researchers (Melezhik
246 and Fallick, 1996). The potential controls of this distribution are discussed below. Firstly,
247 the quantities of concretion-bearing units and preserved marine sedimentary formations
248 are compared to determine if variability can be explained simply by changes in the
249 amount of rock preserved. Then, the major shifts in concretion carbon isotope
250 composition are assessed in the context of potential controls on early marine diagenesis
251 and mineralization.

252

253 **4.1. Insights from the concretion record**

254 The ability to assess the evolution of Earth-surface environments is increasingly
255 challenging as we move back in time due to the limited preservation of older rocks. In
256 addition, ongoing research shows that the mass of preserved sedimentary rock is not
257 readily explained by erosive processes alone. Instead, changes in the Earth-surface
258 system have likely impacted the production of sedimentary rock through time (Husson
259 and Peters, 2018; Ronov et al., 1980). Reconstructions of the temporal abundance of
260 passive margins (Bradley, 2008) and the quantity and volume of marine sedimentary rock
261 formations (preserved on the North American continent) correlate with the quantity of
262 concretion-bearing units (Supplementary Figure 4). Therefore, an environmental signal
263 cannot be confidently identified even though a clear temporal change in concretion-
264 containing units is evident. The concretion abundance record may also be obscured by
265 reporting biases in the literature, the dominant data source for this compilation. As a
266 result, the remaining discussion focuses on concretion carbon isotope data ($\Delta^{13}\text{C}_{\text{con-sw}}$)
267 and potential controls on its variability.

268 The carbon isotope composition of a carbonate concretion is inherited from the
269 porewater DIC from which it precipitates. Since there is only minimal isotope
270 fractionation associated with carbonate mineral production (Emrich et al., 1970; Ohmoto
271 and Rye, 1979), carbonate concretions provide a unique proxy for ancient diagenetic
272 settings. The carbon isotope composition of DIC in porewater reflects a mixture of
273 carbon derived from seawater, the oxidation of organic matter and the oxidation of
274 methane. In addition, methanogenesis exhibits a significant isotope fractionation
275 (Whiticar, 1999) that can further impact porewater DIC. The ranges in isotope

276 composition expressed in marine sediment porewaters result from the relative importance
277 of these different reactions in addition to the transport of carbon-containing reactants and
278 products (Zeebe, 2007). Oxidation- and organic matter-dependent reactions appear to
279 typify much of Earth history, as evidenced by the widespread occurrence of negative
280 values of $\Delta^{13}\text{C}_{\text{con-sw}}$. These reactions require external reactant(s), potentially including
281 aqueous sulfate and particulate iron oxide, and organic matter and/or methane carbon
282 sources. A growing body of research provides insight into the relative temporal
283 abundances of some of these phases. The following discussion explores reactant
284 variability and then connects these trends to specific characteristics of the $\Delta^{13}\text{C}_{\text{con-sw}}$
285 record to evaluate the evolution of marine diagenetic environments.

286

287 **4.2. Organic matter as a carbon source for carbonate precipitation**

288 The dominant concretion-forming mechanisms in marine sediments involve the
289 anaerobic degradation of organic matter or methane (Claypool and Kaplan, 1974;
290 Coleman, 1993; Irwin et al., 1977). Methane primarily forms by the degradation of
291 organic matter, either directly through fermentation reactions or indirectly through the
292 reduction of carbon dioxide derived from organic matter (Koyama, 1963; McCarty,
293 1964). Therefore, all of the major reaction pathways that lead to concretion
294 precipitation involve organic matter in one way or another.

295 The amount of marine carbon buried as organic matter has changed through time
296 (Figure 5), partially in concert with shifts in the oxidation state of Earth's surface (Krause
297 et al., 2022; Krissansen - Totton et al., 2021; Planavsky et al., 2022). Our ability to assess
298 carbon burial relies primarily on temporal changes in the carbon isotope compositions of

299 primary marine carbonates, which approximately record the isotope composition of
300 oceanic DIC at the time of deposition (Schidlowski et al., 1975). Assuming that marine
301 carbonate $\delta^{13}\text{C}$ changes reflect steady-state oceanic inorganic carbon budgets, increases
302 correspond to enhanced organic carbon burial whereas decreases reflect increased organic
303 carbon destruction (i.e., oxidation) (Kump and Arthur, 1999). Although the $\delta^{13}\text{C}$
304 composition of limestones and dolostones preserved in the geologic record may not
305 faithfully record original marine conditions (e.g., Knauth and Kennedy, 2009), long-lived
306 and global positive carbon isotope excursions are difficult to explain without invoking
307 primary marine drivers. In particular, the ~2.3 to 2.1 Ga Lomagundi excursion
308 corresponds to a large $\sim +10\%$ carbonate carbon isotope swing (e.g., Schidlowski et al.,
309 1976) thought to be related to massive deposition of organic matter and an increase in
310 atmospheric O_2 (e.g., Eguchi et al., 2020; Karhu and Holland, 1996). Although the
311 Lomagundi positive isotope excursion has been interpreted as a diagenetic signal related
312 to methane production (Hayes and Waldbauer, 2006), contemporaneous trends in sulfur
313 and sulfur isotope geochemistry are more parsimoniously interpreted as consistent with a
314 primary origin (Planavsky et al., 2012). The Lomagundi event overlaps with the
315 beginning of the concretion-abundant interval between ~2.15 to 1.75 Ga (Figure 1a, b)
316 (Melezhik and Fallick, 1996). In addition to enhanced organic matter burial,
317 contemporaneous changes in the redox state of the oceans at this time may have yielded
318 complementary conditions required to stimulate sedimentary diagenesis, such as the
319 introduction of other oxidants to Earth's surface environment (see section 4.3 below).
320 Similar, long-lived primary carbonate positive $\delta^{13}\text{C}$ values ($\geq +5\%$) occur
321 between glacial intervals in the post-~800 Ma Cryogenian Period (Halverson et al.,

322 2005). These ^{13}C -enriched values are likewise interpreted to represent the enhanced
323 burial of organic matter (Derry et al., 1992; Des Marais et al., 1992) and recent modeling
324 results support these findings (Kipp et al., 2021; Krause et al., 2022; Krissansen - Totton
325 et al., 2021; Planavsky et al., 2022). Beginning about the same time (~750 Ma) and
326 extending toward the Proterozoic–Cambrian boundary, a transition in clay mineral
327 production may have facilitated enhanced burial of organic matter (Kennedy et al., 2006;
328 Kennedy et al., 2002). However, the direct impacts of this transition on atmospheric
329 oxygen contents have been challenged (Tosca et al., 2010). In addition, labile organic
330 matter that is buried in clay-rich sediments can be protected from degradation (Keil et al.,
331 1994), complicating the ability to predict potential impacts of secular changes in clay
332 production on shallow diagenetic environments.

333 Temporal variability in the total organic carbon (TOC) contents of marine shales
334 also provides support for fluctuating organic carbon burial (Och and Shields-Zhou, 2012;
335 Sperling and Stockey, 2018). Importantly, TOC contents increase significantly across the
336 Neoproterozoic–Cambrian boundary and remain relatively high throughout the
337 Phanerozoic (Sperling and Stockey, 2018) as also supported by modeled reconstructions
338 of organic matter burial rates (Krause et al., 2022; Krissansen - Totton et al., 2021;
339 Planavsky et al., 2022). Shallow-marine diagenesis may have been stimulated as a result
340 of this high organic carbon burial rate.

341 Recent work has also revealed a profound shift in the nature of marine organic
342 matter between the Cryogenian “Snowball Earth” glacial intervals (~659 to 645 Ma).
343 Biomarker data suggest a transition from a dominantly bacterial to a bacterial and
344 eukaryotic marine planktonic biosphere (Supplementary Figure 5) (Brocks et al., 2017).

345 This expansion in marine biosphere diversity may have heralded contemporaneous
346 changes in organic matter reactivity. Organic matter reactivity impacts the efficiency of
347 remineralization (e.g., Burdige, 2007) and can influence degradation pathway (Meister et
348 al., 2013). However, the relationship between organic matter source (eukaryotic versus
349 non-eukaryotic) and general reactivity remains poorly understood. Therefore, the addition
350 of significant eukaryotic biomass may or may not have increased the reactivity of organic
351 matter and thus stimulated shallow diagenesis. The record of carbonate concretions since
352 ~659 to 645 Ma exhibits its own interesting trends, perhaps related to two subsequent
353 biological transitions, the appearance and proliferation of metazoans and land plants
354 (Supplementary Figure 5).

355 Partially decayed carcasses of animals, including bones and calcium carbonate or
356 phosphate shells, sometimes occur within carbonate concretions (El Albani et al., 2001;
357 Gaines et al., 2005; Yoshida et al., 2015). Such materials may have provided triggers for
358 localized remineralization and carbonate precipitation since the latest Neoproterozoic.
359 The large accumulation of organic matter associated with decaying animal carcasses
360 provides a local source for anaerobic degradation processes that can cause focused
361 alkalinity increase and thus facilitate carbonate formation (e.g., Duck, 1995). Inorganic
362 mineral phases (shell calcite, aragonite, or phosphate and bone) can also provide
363 nucleation sites for precipitation due in part to the reduced thermodynamic hurdles
364 related to mineral formation on preexisting crystalline materials (Berner, 1980;
365 Sunagawa, 1994).

366 The arrival of extensive (plant) terrestrial ecosystems during the Silurian
367 (Supplementary Figure 5) and their expansion thereafter (Gibling and Davies, 2012;

368 Kenrick and Crane, 1997) likely resulted in a more substantial delivery of exogenous
369 organic matter to the oceans. Such remains occur in marine sediments of the Phanerozoic
370 (Sackett et al., 1974). Raiswell and Berner (1986) have demonstrated a shift toward
371 higher C/S ratios in normal marine shales by the Middle Devonian, consistent with
372 increased delivery of terrestrial organic matter (TOM) thereafter. Remineralization of this
373 TOM could promote carbonate concretion authigenesis. Indeed, modern TOM is thought
374 to provide a significant portion of the total organic carbon budget, particularly in coastal
375 marine sediments (Burdige, 2005; Schlünz and Schneider, 2000). However, TOM may be
376 less reactive than marine organic matter (Aller et al., 1996; Burdige, 2005; Hedges et al.,
377 1997), potentially obscuring the potential impacts of increased delivery. Regardless, such
378 a fundamental shift in carbon sources to marine sediments is likely to have impacted
379 shallow marine diagenetic processes in shelf and slope depositional settings.

380

381 **4.3. Oxidant availability and its influence on organic matter remineralization**

382 Diagenetic processes in shallow marine sediments (including concretion
383 formation) are impacted by the abundance of organic carbon (Arndt et al., 2013), the
384 availability and nature of which has likely changed through geologic time (see above).
385 Remineralization reactions may or may not require additional external oxidant and thus
386 the fate of buried organic matter is variably tied to oxidant availability. The temporal
387 variability of select oxidants, including sedimentary iron oxide and marine sulfate
388 contents (recognized as important in organic matter remineralization and carbonate
389 authigenesis) is discussed in this section.

390 The idea that Earth’s surface has experienced progressive oxygenation is widely
391 accepted. The structure of this oxygenation however, remains a topic of considerable
392 debate. In addition, progressive oxygenation likely impacted the abundances of specific
393 oxidants through time differently. These oxidant budgets in turn likely imparted a first-
394 order control on sedimentary diagenesis of marine environments by stimulating oxidative
395 degradation of organic matter and methane. The temporal evolutions of oxygen and
396 oxidant availability are outlined below.

397

398 4.3.1 Oxygen (O₂)

399 Atmospheric oxygen concentrations likely provide a first-order control on the
400 oxidation state and oxidant capacity of surface environments (both terrestrial and
401 marine). The oxygen content of the atmosphere is thought to have increased as a result of
402 two major oxygenation events. The first of these corresponds to the ~2.5–2.3 Ga Great
403 Oxidation Event (GOE) and is at least casually linked to photosynthetic O₂ buildup
404 (Holland, 2002). This earlier oxygen increase, however, was probably not permanent,
405 terminating with a return to lower oxygen conditions (Bekker and Holland, 2012; Partin
406 et al., 2013). The second increase in oxygen content is thought to have occurred during
407 the Late Neoproterozoic to early Cambrian (Chen et al., 2015; Sahoo et al., 2012; Scott et
408 al., 2008), may have resulted in the ventilation of portions of the deep ocean and heralded
409 the oxygen-rich conditions exhibited today (Lyons et al., 2014). Phanerozoic atmospheric
410 oxygen contents have also fluctuated, albeit at a higher level (between ~10-100% present
411 atmospheric level) (e.g., Berner and Canfield, 1989; Lenton et al., 2018).

412 Despite increasing oxygen concentrations in Earth's atmosphere, the oxidation
413 state of the oceans has exhibited its own complexity, driven in part by the evolving
414 atmospheric boundary condition (Canfield, 1998; Lyons et al., 2009). Prior to the GOE
415 Earth's oceans were predominantly ferruginous (iron(II)-rich) at all depths. After the
416 GOE and until the Proterozoic-Phanerozoic boundary, the redox structure shifted to
417 include oxic and/or sulfidic shallow/mid-depth waters over a persistently ferruginous
418 deep ocean, reflecting in part the delivery of sulfate by oxidative weathering on land and
419 its subsequent reduction to hydrogen sulfide in the water column (Lyons et al., 2009;
420 Planavsky et al., 2011; Poulton et al., 2010). In contrast, generally oxygenated oceans
421 typify the Phanerozoic, with low oxygen and sulfidic marine environments restricted to
422 near-shore, productive and/or restricted settings (Anderson and Devol, 1973; Jacobs et
423 al., 1985; Price and Calvert, 1973; Skei, 1983). These marine transitions are relatively
424 coarse; the fine-scale structure of the redox state of the oceans is potentially much more
425 complex and remains the topic of considerable debate (Lyons et al., 2014). Although the
426 *general* transitions in atmospheric and ocean oxidation state are widely accepted, bottom
427 water concentrations of oxidized phases other than oxygen (including iron oxides and
428 dissolved sulfate) are less well constrained. Oxidant availability at the sediment–water
429 interface impacts the degradation potential of sedimentary organic matter and methane
430 and thus provides a first order control on shallow marine diagenesis.

431

432 4.3.2 Particulate Iron Oxide

433 Iron oxide minerals provide an attractive electron acceptor for organic matter and
434 methane oxidation and subsequent concretion precipitation. Iron reduction metabolisms

435 are thought to be relatively ancient, as indicated by iron isotope compositions in rocks as
436 old as ~3.8 Ga (Supplementary Figure 5) (Craddock and Dauphas, 2011). A compilation
437 of speciation data for shale-hosted iron provides insight into the relative availability of
438 iron oxide through time (Figure 6). The highly reactive iron fraction (FeHR) includes
439 oxide phases (e.g., hematite, magnetite) and reduced phases (e.g., pyrite and iron
440 carbonate minerals) (Raiswell and Canfield, 1998) and thus can be used to assess the
441 original iron oxide content (before and after reduction) of marine sediments (see below).

442 Despite changes in the oxidation state of Earth's surface, broadly expressed as an
443 increase in atmospheric and oceanic oxygen through time, the availability of FeHR in
444 marine shale appears relatively static (Figure 6). Indeed, Sperling et al. (2015) find
445 similarly unchanged iron speciation from the Proterozoic to the early Paleozoic. Iron data
446 have also been screened to exclude samples with FeHR/FeT values greater than 0.38 (the
447 threshold for sediments deposited under anoxic conditions; Poulton and Raiswell, 2002),
448 to remove samples with elevated FeHR that are unrelated to sedimentary Fe³⁺ delivery.
449 This restricted data set likewise does not show significant variability among the time
450 intervals of interest here. However, iron speciation data are not equally available for the
451 different time periods (Sperling et al., 2015). More continuous population of this data set
452 may reveal temporal variability that is missed by this compilation.

453

454 4.3.3 Aqueous Sulfate

455 The understanding of the temporal evolution of marine sulfate concentrations has
456 developed significantly over the past twenty years. This understanding stems from fluid
457 inclusion data (Horita et al., 2002; Lowenstein et al., 2003), sulfur isotope variability

458 (Algeo et al., 2015; Gill et al., 2011; Kah et al., 2004; LaFlamme et al., 2021; Planavsky
459 et al., 2012) and fractionation magnitude experiments (Habicht et al., 2002), modeling
460 (Berner, 2004; Fakhraee et al., 2018; Fakhraee et al., 2019; Krause et al., 2022; Shi et al.,
461 2022) and the occurrence of marine evaporite deposits in the geologic record (Evans,
462 2006; Halevy et al., 2012; Wortmann and Chernyavsky, 2007). Sulfate concentrations
463 (Figure 7) exhibit a transient rise in association with the ~2.3 to 2.1 Ga Lomagundi
464 interval (Planavsky et al., 2012; Salop, 1982; Schröder et al., 2008) which overlaps with
465 the beginning of the relatively concretion-abundant interval at ~2.15 to 1.75 Ga
466 (Melezhik and Fallick, 1996). Evaporite paragenetic data that show halite saturation prior
467 to gypsum/anhydrite may indicate a return to low sulfate concentrations by ~1.9 Ga
468 (Blättler et al., 2018; Pope and Grotzinger, 2003).

469 At ~1.7 Ga sulfate concentrations have been estimated at ~1.5 mM and remain
470 below ~5 mM until ~750 Ma where sulfate concentrations increase to $\sim 10 \pm 5$ mM
471 (Blättler et al., 2020; Kah et al., 2004; Krause et al., 2022), similar to the Phanerozoic
472 minimum (Horita et al., 2002; Lowenstein et al., 2003). Within the Phanerozoic, sulfate
473 concentrations vary (Figure 7b), reaching up to ~28 mM in the modern (Horita et al.,
474 2002; Lowenstein et al., 2003). This variability is broadly characterized by two stepwise
475 increases, one occurring across the Ediacaran–Cambrian boundary where concentrations
476 are thought to have reached up to ~10 mM in the early Cambrian and the other beginning
477 in the late Paleozoic. The timing of late Paleozoic sulfate increase varies depending on
478 literature source; however most reconstructions display an increase at the beginning or
479 within the Carboniferous. Note that the sulfate records presented in Figure 7 may not
480 include brief episodes of sulfate fluctuation such as those associated with the Permian–

481 Triassic interval (Luo et al., 2010; Song et al., 2014) and Cretaceous Ocean Anoxic
482 Events (Adams et al., 2010; Ohkouchi et al., 1999).

483

484 **4.4. Evolving carbon isotope distribution in shallow diagenetic environments**
485 **throughout Earth history**

486 As discussed above, $\Delta^{13}\text{C}_{\text{con-sw}}$ provides insights into temporal changes in shallow
487 marine diagenesis, particularly when isotope compositions exceed or fall below threshold
488 values. Data mean, maximum, minimum and range values for different age intervals
489 demonstrate significant temporal variability (Figure 4), perhaps related to evolving
490 marine diagenetic environments. It is important to note that the data-limited
491 Neoproterozoic and older record may be more susceptible to biases associated with local
492 rather than global environmental controls (depositional environment, etc.) compared to
493 the data-replete younger record. We acknowledge that additional data collection may help
494 resolve this potential bias and interpret the concretion carbon isotope variability
495 demonstrated here in the context of broad temporal changes in Earth's surface
496 environment. A lack of clear changes in reactive/oxide iron phases (Figure 6,
497 Supplementary Figure 6) suggests that particulate iron oxides do not drive $\Delta^{13}\text{C}_{\text{con-sw}}$
498 variability. Thus, concretion isotope evolution is discussed in the context of other
499 potential controls in the following discussion.

500 Prior to ~2.15 Ga, concretions yield values that overlap with or exceed
501 contemporaneous seawater values (i.e., $\Delta^{13}\text{C}_{\text{con-sw}} \geq 0\%$, Figure 3). The earliest
502 concretions (~2.8 Ga) express positive $\Delta^{13}\text{C}_{\text{con-sw}}$ values indicating formation as a result
503 of methanogenesis (Dix et al., 1995). Molecular clock studies suggest early evolution of

504 methanogenesis metabolisms, perhaps originating at ~3.8 to 4.1 Ga (Supplementary
505 Figure 5) (Battistuzzi et al., 2004), well before the formation of these earliest known
506 concretions. Later Archean concretions within ~2.6 Ga rocks express $\delta^{13}\text{C}$ values that do
507 not differ significantly from seawater values (Figure 3a), suggesting a dominantly marine
508 DIC or primary carbonate mineral dissolution source.

509 The prevalence of near neutral $\Delta^{13}\text{C}_{\text{con-sw}}$ values during the Precambrian (Figure
510 3) may reflect the combined effects of low sulfate availability and high marine DIC
511 contents. As confirmed by model results, lower sulfate concentrations limit porewater
512 oxidation of sedimentary organic matter and methane and preclude severe decreases in
513 $\delta^{13}\text{C}_{\text{DIC}}$ (Figure 8 and Supplementary Figure 7) and thus $\Delta^{13}\text{C}_{\text{con-sw}}$. This is consistent
514 with previous modelling work exploring impacts of low sulfate concentration on
515 porewater and authigenic carbonate $\delta^{13}\text{C}$ (Laakso and Schrag, 2020). Marine DIC
516 contents may have been relatively high early in Earth history as supported by muted
517 variability in marine $\delta^{13}\text{C}$ (Bartley and Kah, 2004) and carbonate fabrics that indicate
518 rapid precipitation (Grotzinger and James, 2000). Under elevated marine DIC conditions,
519 shallow porewaters would be buffered against isotope modification by diagenesis. The
520 potential impacts of an increased marine DIC reservoir are demonstrated in Figure 9.
521 Importantly, under low sulfate and high marine DIC conditions, porewater $\delta^{13}\text{C}_{\text{DIC}}$
522 variability is diminished, manifested primarily as an increase in minimum values. Under
523 higher sulfate concentrations, the impacts of increasing marine DIC are less substantial.
524 Therefore, high marine DIC values during the Precambrian may have contributed to the
525 limited variability observed in $\Delta^{13}\text{C}_{\text{con-sw}}$.

526 Conclusively oxidation-derived carbonate concretions first appear at ~2.15 Ga. In
527 fact, all concretion-hosting units between ~2.15 and 1.75 Ga include samples with
528 predominantly negative $\Delta^{13}\text{C}_{\text{con-sw}}$ (Figure 3a). The $\Delta^{13}\text{C}_{\text{con-sw}}$ values extend down to ~ -
529 25‰, consistent with at least partial carbon incorporation from organic matter, methane
530 or both (Melezhik and Fallick, 1996). The $\Delta^{13}\text{C}_{\text{con-sw}}$ value of Lomagundi concretions
531 (and other Precambrian-aged concretions) is constrained by nearby limestones considered
532 to reflect primary marine DIC (see Results). In this regard, the ^{13}C -depleted $\Delta^{13}\text{C}_{\text{con-sw}}$
533 values of the Lomagundi interval should not be impacted by potential facies dependency
534 of primary $\delta^{13}\text{C}$ values (Prave et al., 2022). In addition, the limestone $\delta^{13}\text{C}$ values used to
535 constrain $\Delta^{13}\text{C}_{\text{con-sw}}$ do not exceed +5.4‰ (Supplementary Table 1) and thus do not drive
536 the low $\Delta^{13}\text{C}_{\text{con-sw}}$ during this interval.

537 Intriguingly, the Lomagundi interval post-dates the GOE and coincides with a
538 transient increase in marine sulfate concentration (Planavsky et al., 2012). Concretions of
539 the Lomagundi interval express $\Delta^{13}\text{C}_{\text{con-sw}}$ values significantly lower than the preceding
540 and following Precambrian (Figure 5), perhaps testament to a significant control of
541 increased marine sulfate on porewater DIC (see Figure 8a). Concretions with the lowest
542 $\Delta^{13}\text{C}_{\text{con-sw}}$ values formed during the highest marine sulfate concentrations (up to ~ 11
543 mM, Fakhraee et al., 2019; Planavsky et al., 2012) of the Lomagundi interval (Figure 7a).
544 Thereafter, values increase but remain negative until ~1.75 Ga, despite an apparent
545 massive drawdown in marine sulfate at the tail end of the Lomagundi event (Planavsky et
546 al., 2012). Unfortunately, marine sulfate concentrations are not well resolved between the
547 sulfate “crash” and ~1.75 Ga. Constraining sulfate concentrations in this interval would
548 provide additional insight.

549 The next occurrence of carbonate concretions is reported in the ~1.4 Ga
550 Xiamaling Formation. These concretions express $\Delta^{13}\text{C}_{\text{con-sw}}$ near 0‰, interpreted to
551 represent a marine DIC carbon source (Liu et al., 2019) rather than one that requires
552 oxidative processes. Sulfate concentrations were relatively low at 1.4 Ga (Figure 7),
553 perhaps explaining the return to near neutral $\Delta^{13}\text{C}_{\text{con-sw}}$. The next youngest reported
554 concretions occur in shales of the ~745 Ma Kwagunt Formation of the Chuar Group
555 (Dehler et al., 2005). These concretions exhibit $\Delta^{13}\text{C}_{\text{con-sw}}$ values ranging from ~ -15 to ~
556 -7‰ (supplemented with new data reported here) and a return to at least partial carbon
557 derivation from the oxidation of organic matter and/or methane. Intriguingly, sulfate
558 concentrations may have been relatively high during this time interval (Kah et al., 2004),
559 which was followed by subsequent decreases associated with Neoproterozoic glacial
560 intervals (Hurtgen et al., 2002). Thus prior to the Cambrian, low $\Delta^{13}\text{C}_{\text{con-sw}}$ values
561 coincide with intervals of transient high marine sulfate concentrations.

562 Negative $\Delta^{13}\text{C}_{\text{con-sw}}$ values dominate the relatively well-resolved Phanerozoic
563 record thereafter (Figure 3), when marine sulfate concentrations were high. Indeed, mean
564 $\Delta^{13}\text{C}_{\text{con-sw}}$ values are significantly lower in the Phanerozoic compared to non-Lomagundi
565 Precambrian counterparts (Figure 4a). Phanerozoic mean $\Delta^{13}\text{C}_{\text{con-sw}}$ values range from ~ -
566 7.9 to -5.6‰ whereas the non-Lomagundi Precambrian mean $\Delta^{13}\text{C}_{\text{con-sw}}$ value is ~ -0.5‰
567 (Figure 4). This decrease demonstrates the oxidative impact of a growing marine sulfate
568 reservoir. Intriguingly, the mean $\Delta^{13}\text{C}_{\text{con-sw}}$ value remains relatively stable throughout the
569 Phanerozoic, despite a subsequent increase in marine sulfate during the mid- to late
570 Paleozoic. The static Phanerozoic mean $\Delta^{13}\text{C}_{\text{con-sw}}$ values developed, in part, as a result of
571 the expansion of the concretion carbon isotope record to include compositions both

572 depleted and enriched in ^{13}C (Figure 4). The implications of this expansion as related to
573 changing minimum and maximum $\Delta^{13}\text{C}_{\text{con-sw}}$ are discussed below.

574 Early Paleozoic concretions (Cambrian to Devonian samples) express a minimum
575 $\Delta^{13}\text{C}_{\text{con-sw}}$ value that extends down to $\sim -25\%$, the approximate concurrent organic matter
576 composition. This minimum value is similar to that of the Lomagundi interval (Figure 4,
577 Supplementary Table 5). Reported marine sulfate concentrations are comparable for these
578 two time intervals, reaching up to ~ 10 mM (Figure 7). This similarity underscores the
579 control of marine sulfate concentrations on $\Delta^{13}\text{C}_{\text{con-sw}}$.

580 $\Delta^{13}\text{C}_{\text{con-sw}}$ values do not drop below -25% until ~ 325 Ma (Figures 3 and 4),
581 following reported elevated marine sulfate concentrations in the Carboniferous (Bernier,
582 2004; Gill et al., 2007; Halevy et al., 2010) and representing the first conclusive evidence
583 for methane oxidation-derived inorganic carbon. Similar low isotope compositions persist
584 throughout the remaining record (see minimum $\Delta^{13}\text{C}_{\text{con-sw}}$ values in Figure 4). These data
585 imply that the AOM pathway has been an important methane consumption and
586 concretion producing reaction since at least ~ 325 Ma and perhaps earlier (methane
587 oxidation-derived concretions need not produce values below -25% if other carbon
588 sources also contributed). Modern marine sediments often show porewater $\delta^{13}\text{C}_{\text{DIC}}$
589 minima that approach but do not drop below the organic matter value despite active
590 AOM, suggesting quantitative oxidation of locally produced methane by sulfate in
591 shallower sediments (Meister et al., 2019). Modeling results indicate that both high
592 marine sulfate and an external source of methane are required to produce isotope
593 compositions significantly lower than -25% (Figure 8 and Supplementary Figure 7). The
594 degree of ^{13}C depletion below -25% ultimately depends on marine sulfate content, the

595 amount of methane entering the system and its $\delta^{13}\text{C}$. Perhaps not surprisingly, non-
596 concretionary methane cold-seep authigenic carbonates express similarly diagnostic, low
597 $\delta^{13}\text{C}$ values at about the same time. The transition to conclusively methane-oxidation-
598 derived seep carbonates has likewise been attributed to increased marine sulfate
599 concentrations (Bristow and Grotzinger, 2013). The Paleozoic appearance of
600 diagnostically low concretion and seep-carbonate $\Delta^{13}\text{C}_{\text{con-sw}}$ values did not result from the
601 concurrent evolution of organisms capable of AOM as these lineages are relatively
602 ancient, perhaps existing since ~2.6 to 2.8 Ga (Supplementary Figure 5) (Battistuzzi et
603 al., 2004; Hinrichs, 2002).

604 The relationship of AOM-derived authigenic carbonate to temporal delivery of
605 external methane is more difficult to resolve. We speculate that the generation of
606 significant methane accumulations may in part be related to enhanced organic carbon
607 burial in the Phanerozoic (from marine and/or terrestrial sources, see above). This
608 methane could then be delivered to shallow sediments relatively quickly (perhaps through
609 methane hydrate dissolution, for example) and oxidized to generate the severe ^{13}C
610 depletions diagnostic of AOM. A negative correlation between mean organic carbon
611 burial rates and minimum $\Delta^{13}\text{C}_{\text{con-sw}}$ values (that also drop below -25% , Figure 10)
612 supports this assertion. Constraining the temporal distribution of large methane reserves
613 is beyond the scope of this work, but may provide additional insight.

614

615 **4.5. Identifying dominant controls on carbon isotope minima and maxima of**
616 **inorganic carbon**

617

618 *4.5.1. $\delta^{13}C$ minima in the AOM zone*

619 As discussed above, sulfate appears to play an integral role in governing Earth's
620 shallow marine diagenetic environments. The relationship between marine sulfate
621 concentration and concretion isotope compositions is emphasized in Figure 8d. This plot
622 demonstrates a strong negative correlation between the sulfate content and minimum
623 $\Delta^{13}C_{\text{con-sw}}$ during the time intervals discussed above. Encouragingly, this correlation
624 mimics the porewater minimum $\delta^{13}C_{\text{DIC}}$ model results of Figure 8c where the impacts of
625 changing marine sulfate contents are displayed under variable external methane flux.
626 Ultimately these results demonstrate that marine sulfate concentrations and the delivery
627 of external methane dictate the minimum $\delta^{13}C_{\text{DIC}}$ (and $\Delta^{13}C_{\text{con-sw}}$) values generated in the
628 AOM zone.

629

630 *4.5.2. $\delta^{13}C$ maxima in the methanogenic zone*

631 Collectively, Phanerozoic concretions express $\Delta^{13}C_{\text{con-sw}}$ values that are consistent
632 with oxidation and methane-producing reactions. The increase in the range in isotope
633 compositions within the Phanerozoic is manifested as both a decrease in minimum and an
634 increase in maximum values (Figures 3 and 4). As discussed above, sulfate appears to be
635 an important external oxidant as revealed by relationships between sulfate concentration
636 and $\Delta^{13}C_{\text{con-sw}}$ data. However, the coincident increase in the abundance of conclusively
637 methanogenesis-derived concretions (as indicated by positive $\Delta^{13}C_{\text{con-sw}}$) is not
638 straightforwardly attributable to increasing sulfate concentrations.

639 It has been proposed that an increase in the quantity of organic matter delivered to
640 the sediment-water interface may dictate the relative importance of concretion-yielding

641 diagenetic reactions, such that higher amounts promote organic matter persistence to the
642 deeper methanogenesis zone (Mozley and Burns, 1993). In this regard, the increase in the
643 quantity of organic matter in Phanerozoic compared to Neoproterozoic marine sediments
644 recognized by Sperling and Stockey (2018) and supported by model reconstructions
645 (Krause et al., 2022; Krissansen - Totton et al., 2021; Planavsky et al., 2022) may have
646 promoted the expansion of methanogenesis (Sivan et al., 2007). However, maximum
647 $\Delta^{13}\text{C}_{\text{con-sw}}$ values do not show significant correlation with organic carbon burial (Figure
648 11a). Figure 11b and Supplementary Figure 8 show variability in modeled maximum
649 $\delta^{13}\text{C}_{\text{DIC}}$ values as a function of TOC deposited at the seafloor. Note that the global
650 organic carbon burial rate does not dictate the specific quantity of TOC deposited on the
651 seafloor at any given location. However, broad increases in organic carbon burial are
652 likely to lead to generally higher TOC delivery globally, explaining the motivation
653 behind panel comparisons in Figure 11. As initial TOC increases so does the maximum
654 $\delta^{13}\text{C}_{\text{DIC}}$; however isotope compositions do not exceed $\sim +15\text{‰}$ (Figure 12b,
655 Supplementary Figure 8). Meister et al. (2019) demonstrate this maximum threshold
656 under modern marine sulfate concentrations (28 mM) and new model results show that
657 lower sulfate concentrations do not significantly increase $\delta^{13}\text{C}_{\text{DIC}}$ maximum values. Thus
658 the $\Delta^{13}\text{C}_{\text{con-sw}}$ values above $\sim +20\text{‰}$ commonly expressed in the Phanerozoic record
659 cannot be accounted for by organic carbon burial alone.

660 It has been demonstrated that increased sedimentation rates lead to faster organic
661 matter burial and degradation in the deeper methanogenesis zone (Burns and Baker,
662 1987; Pisciotto and Mahoney, 1981; Scotchman, 1991), largely due to limitations

663 associated with sulfate diffusion from the overlying water column. As yet, no data have
664 been reported that indicate an increased sedimentation rate in the Phanerozoic
665 compared to earlier times. Organic matter reactivity can also impact degradation
666 mechanisms. Similar to increased sedimentation rate, less reactive organic matter
667 degrades more slowly and can persist to deeper sediment depths to experience
668 preferential degradation in the methanogenesis zone (Meister et al., 2019). Thus, higher
669 proportions of more refractory organic matter can cause porewater DIC to become more
670 ^{13}C -enriched with depth. The evolution of organic matter reactivity is not well known,
671 but the arrival and diversification of terrestrial plants may have prompted the delivery of
672 less reactive organic material (Aller et al., 1996; Burdige, 2005; Hedges et al., 1997) to
673 marginal environments since the Silurian (Kenrick and Crane, 1997; Raiswell and
674 Berner, 1986). Maximum $\Delta^{13}\text{C}_{\text{con-sw}}$ values, however, show an increase well before the
675 appearance of land plants (Supplementary Figure 5). Furthermore, significant decreases
676 in organic matter degradation rate are unable to account for porewater DIC ^{13}C
677 enrichments above $\sim +10\text{‰}$ in the methanogenesis zone (Meister et al., 2019) like those
678 expressed in the concretion record. Whereas sedimentation rate and organic matter
679 quantity and reactivity may impact organic matter degradation mechanisms, these factors
680 alone cannot explain the observed data.

681 Another more speculative explanation involves an increase in the magnitude of
682 carbon isotope fractionation during methanogenesis. Fractionation factors between
683 methane and DIC ($\alpha_{\text{methane-DIC}}$) determined from culture and modern porewater data are
684 between 0.95 and 1.0 (Londry et al., 2008; Whiticar et al., 1986). Some modern marine
685 sediments, however, express $\delta^{13}\text{C}_{\text{DIC}}$ maxima that are difficult to reconcile with low

686 fractionation magnitudes (Meister et al., 2019). In addition, the concretion record
687 suggests that higher maximum porewater $\delta^{13}\text{C}_{\text{DIC}}$ compositions occurred in more recent
688 marine sediments, exceeding the values that can be reached by using the experimentally
689 determined fractionation factors mentioned above. It has been suggested that substrate
690 limitation during AOM promotes reaction reversibility as part of the Wood-Ljungdahl
691 pathway and that this reversibility can lead to isotopic fractionation that approaches
692 theoretical equilibrium magnitudes (Yoshinaga et al., 2014). Similar reversibility may
693 affect isotope fractionation during methanogenesis as suggested by some culture
694 experiments conducted under substrate limited conditions (Botz et al., 1996 ; see
695 comparison in Meister and Reyes (2019)) and isotope separations between co-occurring
696 porewater DIC and methane recognized in porewaters of many marine sediments
697 (e.g.,(Galimov and Kvenvolden, 1983; Heuer et al., 2009; Meister et al., 2019; Paull et
698 al., 2000; Pohlman et al., 2008) . It is conceivable that under extreme substrate limitation
699 (which is common in sub-seafloor environments) the fractionation factor may approach
700 the theoretical low-temperature equilibrium value ($\alpha_{\text{methane-DIC}} = 0.93$,(Bottinga, 1969);
701 Horita (2001)).

702 To explore the effect of the fractionation factor on maximum $\delta^{13}\text{C}_{\text{DIC}}$, model
703 experiments were conducted at variable $\alpha_{\text{methane-DIC}}$ (from 0.92 to 0.98, Supplementary
704 Figures 9 and 10). In these experiments, methane was sourced entirely from within the
705 model domain (i.e., no external methane flux imposed). Maximum $\delta^{13}\text{C}_{\text{DIC}}$ values
706 increased at lower fractionation factors, reaching up to $\sim +9\text{‰}$ (at $\alpha_{\text{methane-DIC}} = 0.92$).
707 However, in this most extreme scenario the isotopic separation between methane and
708 DIC becomes very high ($\sim 100\text{‰}$) and exceeds differences commonly observed in

709 measured profiles. Increasing the external methane flux did not significantly change
710 maximum $\delta^{13}\text{C}_{\text{DIC}}$ when external methane was assigned the $\delta^{13}\text{C}$ composition of the in-
711 situ methane produced at the bottom of the model domain (Supplementary Figures 9 and
712 10). Thus, increased isotope fractionation alone cannot account for the highly positive
713 $\Delta^{13}\text{C}_{\text{con-sw}}$ values expressed in the concretion record.

714 One mechanism that could promote extreme ^{13}C enrichment of porewater DIC
715 involves equilibration with externally derived methane exhibiting a relatively high $\delta^{13}\text{C}$.
716 Such methane can form through thermogenic processes and exhibit isotope compositions
717 near $\sim -40\%$. Hypothetically, equilibration between thermogenic methane and DIC could
718 result in $\delta^{13}\text{C}_{\text{DIC}}$ values up to $\sim +30$ to $+40\%$ if the methanogenic reaction is reversible
719 (such that isotope exchange occurs between methane and DIC) and an isotope offset of
720 ~ 70 to 80% is maintained. Such a process may in part explain the very high $\delta^{13}\text{C}_{\text{DIC}}$
721 values recognized at some Cascadia Margin sites (Heuer et al., 2009), although other
722 factors including gas escape to the water column may also play a role (Birgel et al., 2015;
723 Meister et al., 2019). Despite the poorly understood complexities involved in isotope
724 fractionation during methanogenesis and the potential role of equilibration, the
725 mechanisms of ^{13}C enrichments and depletions in porewater DIC may both involve the
726 influx of external methane. As argued above, methane formation (thermogenic or
727 biogenic) may have been stimulated as a result of enhanced organic carbon burial during
728 the Phanerozoic, thus providing a singular driver for the roughly contemporaneous
729 expansion in $\Delta^{13}\text{C}_{\text{con-sw}}$ range.

730

731 **4.6. Implications for the $\delta^{13}\text{C}$ of authigenic carbonate**

732 Modern authigenic carbonates form within marine sediments as a result of similar
733 reactions to those proposed for carbonate concretions. In fact, carbonate concretions are
734 thought to represent ancient analogs to modern authigenic carbonates (Loyd and
735 Berelson, 2016). This connection has been confounded in part as a result of the inability
736 to identify core-recovered carbonate as concretionary in nature (core sampling limits the
737 ability to characterize the three-dimensional structure of large objects). The similarity
738 between the carbon isotope composition of authigenic carbonate ($\delta^{13}\text{C}_{\text{auth}}$) and Triassic to
739 Holocene $\Delta^{13}\text{C}_{\text{con-sw}}$ values (Figure 4) provides further support to the proposed analogy.
740 Thus, the concretion-based record presented here may provide insight into the evolution
741 of $\delta^{13}\text{C}_{\text{auth}}$ through time.

742 As with the carbon isotope composition of carbonate concretions, $\delta^{13}\text{C}_{\text{auth}}$ is likely
743 to have changed as a result of broad changes in the oxidation state of marine bottom
744 waters. Previous work aimed at exploring the impact of authigenic carbonate
745 precipitation on global carbon budgets and marine $\delta^{13}\text{C}_{\text{DIC}}$ hinges intimately on
746 constraining an average $\delta^{13}\text{C}_{\text{auth}}$ value (Schrag et al., 2013). Indeed, Schrag et al. (2013)
747 and Laakso and Schrag (2020) propose that average $\delta^{13}\text{C}_{\text{auth}}$ values may have been
748 different in the past and this inference is supported by the Precambrian $\Delta^{13}\text{C}_{\text{con-sw}}$ record.
749 When data outside the Lomagundi interval are considered, mean Precambrian $\Delta^{13}\text{C}_{\text{con-sw}}$
750 values differ significantly from other time intervals (Figure 4). The average Precambrian
751 non-Lomagundi $\Delta^{13}\text{C}_{\text{con-sw}}$ value is very near neutral ($\sim -0.5\text{‰}$) and indistinguishable
752 from contemporaneous primary carbonate. Therefore, according to this concretion data
753 set, burial of Precambrian authigenic carbonate would have had little impact on marine
754 $\delta^{13}\text{C}$ variability. Once marine sulfate concentrations exceeded ~ 5 mM (during brief

755 transient intervals in the Precambrian or otherwise), mean $\Delta^{13}\text{C}_{\text{con-sw}}$ values consistently
756 lie between ~ -10 and $\sim -5\%$. These compositions agree with recent findings of Laakso
757 and Schrag (2020), are comparable to, to somewhat higher than approximate $\delta^{13}\text{C}_{\text{auth}}$
758 values proposed by Schrag et al. (2013), and considerably higher than the estimated
759 modern average $\delta^{13}\text{C}_{\text{auth}}$ value of $-20.5 \pm 3.5\%$, based on compiled pore water
760 geochemical data (Bradbury and Turchyn, 2019). Differences in mean values may in part
761 be explained by the exclusion of non-concretionary, seafloor methane seep carbonates
762 and/or preferential retention of methanogenesis-formed carbonate in the sampled
763 concretion record.

764

765 **5. CONCLUSIONS**

766 Carbonate concretions primarily occur in Phanerozoic rock units and a
767 concretion-rich interval between ~ 2.15 and 1.75 Ga that overlaps with the enigmatic
768 Lomagundi carbon isotope excursion (Melezhik and Fallick, 1996). This distribution may
769 result from preferential formation during these time intervals, but correlation with the
770 abundance of preserved sedimentary rock precludes identification of an environmental
771 signal in the concretion occurrence record. In contrast, the concretion isotope record
772 provides important information about shallow marine diagenetic environments. Negative
773 $\Delta^{13}\text{C}_{\text{con-sw}}$ values dominate the Phanerozoic and Lomagundi interval and correlate with
774 periods exhibiting high marine dissolved sulfate concentrations and organic carbon burial
775 rates. Concretions with conclusively AOM carbon isotope signals appear at ~ 325 Ma and
776 are relatively common in the younger record, likely in response to a Paleozoic rise in
777 marine sulfate concentrations and significant delivery of external methane. The

778 Phanerozoic record also shows an increase in $\Delta^{13}\text{C}_{\text{con-sw}}$ through time perhaps resulting
779 from increased input of thermogenic methane and isotopic equilibration with porewater
780 DIC. Ultimately, the concretion record demonstrates coeval evolution of Earth's primary
781 marine and shallow diagenetic environments, in part related to shifting redox conditions.

782
783

784 **Acknowledgements**

785 We thank Julie Unson and Miguel Rincon for analytical assistance and Mary Droser for
786 providing Chuar Group samples. Jon Husson provided integral rock abundance data from
787 the Macrostrat database. Insightful communications with Peter Mozley, Doug LaRowe,
788 Kristen Bergmann, Eric Sperling, Maggie Osborn and David Ware and early reviews
789 provided by Ben Gill, Leanne Hancock and one anonymous reviewer were highly
790 beneficial to this manuscript.

1230 **Figure Captions**

1231 Figure 1: Abundance of concretion-bearing units through time. a) Entire distribution in
1232 100-Myr age bins. b) 3000 to 1000 Ma, notice concretion-rich interval following the
1233 Archean Proterozoic boundary. c) 950 Ma to present in 25-Myr age bins. Panels b and c
1234 indicate $\delta^{13}\text{C}$ coverage.

1235
1236
1237 Figure 2: Concretion a) mineralogy and b) host lithology. Note scale compression for
1238 1000 Ma and older bins.

1239
1240 Figure 3: $\Delta^{13}\text{C}_{\text{con-sw}}$ variability a) since 3000 Ma and b) since the latest Proterozoic.
1241 Shaded envelope encompasses expected seawater values and dashed line indicates
1242 minimum values for organic matter oxidation (-25%). Normal and septarian concretions
1243 and associated crystal habits indicated by symbols.

1244
1245 Figure 4: $\Delta^{13}\text{C}_{\text{con-sw}}$ a) mean, b) minimum (min.), c) maximum (max.) and d) ranges for
1246 different age intervals. Precambrian data provided with (All) and without (- Lomag.)
1247 Lomagundi-aged samples. Notice decrease in minimum and increase in maximum and
1248 ranges through time.

1249
1250 Figure 5: Marine organic carbon burial and $\Delta^{13}\text{C}_{\text{con-sw}}$. a) Temporal variability since 3000
1251 Ma and b) 600 Ma. Organic carbon burial data after model reconstructions of Planavsky
1252 et al. (2022) and Krissansen - Totton et al. (2021). Organic carbon burial after low

1253 erosion rate, low overbank oxidation results of Planavsky et al. (2022) (Fig. 14a from that
1254 work), other result show similar trends but with potentially different absolute values.

1255
1256
1257 Figure 6: Iron speciation data and $\Delta^{13}\text{C}_{\text{con-sw}}$ (gray symbols). a) all iron data, b) data from
1258 samples with $\text{FeHR}/\text{FeT} \leq 0.38$ wt.%. Notice lack of increase in iron contents through
1259 time and in particular across the Proterozoic-Paleozoic transition. Correlation plots and
1260 iron data references provided in Supplementary Material.

1261
1262
1263 Figure 7: Marine sulfate concentrations and $\Delta^{13}\text{C}_{\text{con-sw}}$ (gray symbols). a) Temporal
1264 variability since 3000 Ma and b) 600 Ma. Sulfate concentrations from Planavsky et al.
1265 (2012), MSR-method of Algeo et al. (2015), Fakhraee et al. (2018), Fakhraee et al.
1266 (2019), Shi et al. (2022), Habicht et al. (2002), Berner (2004), Halevy et al. (2012),
1267 Blättler et al. (2018), Blättler et al. (2020), LaFlamme et al. (2021) and Krause et al.
1268 (2022).

1269
1270
1271 Figure 8: Porewater model results demonstrating potential controls on $\delta^{13}\text{C}_{\text{DIC}}$ and
1272 comparison to concretion record. Solid and dashed gray lines in a-c represent marine DIC
1273 and organic matter $\delta^{13}\text{C}$, respectively. a) impact of marine sulfate content. Note that as
1274 sulfate concentrations increase, both $\delta^{13}\text{C}_{\text{DIC}}$ minimum and maximum values decrease. b)
1275 impact of external methane flux under modern marine sulfate concentrations. External
1276 methane $\delta^{13}\text{C}$ values are assigned the value achieved at the base of the modeled domain,
1277 deviations from this value impact the minimum $\delta^{13}\text{C}_{\text{DIC}}$. Note that as external methane
1278 input increases, $\delta^{13}\text{C}_{\text{DIC}}$ minimum values decrease and yield compositions below the

1279 organic matter $\delta^{13}\text{C}$ value. c) impact of marine sulfate content under variable external
1280 methane flux (ext. CH_4 flux). Increased sulfate contents yield decreased $\delta^{13}\text{C}_{\text{DIC}}$
1281 minimum and maximum values similar to overall trends observed in a. Note that $\delta^{13}\text{C}_{\text{DIC}}$
1282 depletions produce minimum values that drop well below the organic matter $\delta^{13}\text{C}$ value
1283 under high sulfate conditions. Maximum data trends overlap. In a-c, $\alpha_{\text{methane-DIC}} = 0.94$
1284 and the isotopic difference between methane and DIC was maintained at $\sim 75\%$. d)
1285 comparison between marine sulfate concentrations and minimum $\Delta^{13}\text{C}_{\text{con-sw}}$ for the age
1286 groupings discussed in the text. Blue bands represent ranges from Fakhraee et al., 2018,
1287 2019, all other data are sulfate concentration averages. Notice decrease in minimum
1288 isotope compositions with increasing sulfate content, similar to minimum model data in
1289 c. Linear regressions and correlation strengths also provided.

1290
1291
1292 Figure 9: Modeled variability in $\delta^{13}\text{C}_{\text{DIC}}$ as a function of marine DIC content across a
1293 range of marine sulfate concentrations. Increasing marine DIC yields higher $\delta^{13}\text{C}_{\text{DIC}}$
1294 minima except under the 0 mM sulfate condition. This increase is more pronounced at
1295 lower marine sulfate concentrations. The $\delta^{13}\text{C}_{\text{DIC}}$ maxima are relatively invariant.

1296
1297
1298 Figure 10: Comparison between organic carbon burial and minimum $\Delta^{13}\text{C}_{\text{con-sw}}$ for the
1299 age groupings discussed in the text.

1300
1301 Figure 11: Impacts of organic carbon burial on isotope compositions. a) Comparison
1302 between organic carbon burial and maximum $\Delta^{13}\text{C}_{\text{con-sw}}$ for the age groupings discussed
1303 in the text. b) Modeled variability in $\delta^{13}\text{C}_{\text{DIC}}$ as a function of total organic carbon (TOC)

1304 deposited at the sediment water interface. As TOC contents increase $\delta^{13}\text{C}_{\text{DIC}}$ maximum

1305 values increase, but do not exceed $\sim +15\%$.
