Abstract

The equatorial Pacific holds the potential to investigate the climate variability of the Earth as it connects both hemispheres via the atmospheric and oceanic circulation. The modern Equatorial Pacific Intermediate Water (EqPIW) is fed by three end-member components: Southern Ocean Intermediate Water (SOIW), Pacific Deep Water (PDW) and, by a smaller proportion, North Pacific Intermediate Water (NPIW). This modern configuration of end-members in the EqPIW results in low productivity of siliceous phytoplankton in the Eastern Equatorial Pacific (EEP) today as SOIW is depleted in silicic acid compared to other nutrients. An increased primary production during glacials has often been attributed to an enhanced contribution of SOIW to equatorial sub-surface waters. However, there is growing debate over whether SOIW was capable of stimulating glacial equatorial productivity. This is in light of the fact that nutrients appear to have been trapped in glacial Southern Ocean waters. Furthermore, recent studies point towards a change in the lateral and vertical extent of both SOIW and NPIW during glacials, impacting the supply of nutrients to the EEP. Ultimately, the effect of these intermediate water mass changes on equatorial waters remains elusive.

Most upper ocean water mass reconstructions are based on planktonic foraminifera tests. Different foraminiferal species preferentially dwell in distinct water depths and thus, the calcitic tests of these species can be used to infer past climate conditions. However, it has been shown that the Apparent Calcification Depths (ACDs) of foraminiferal species are spatially non-uniform. To-date, there are no ACD reconstructions from the equatorial Pacific based on multinet data. This thesis assesses equatorial foraminiferal ACDs to identify a species suitable to trace nutrient-inflow of extra-tropical intermediate water masses. Using this determined species, this thesis then reconstructs the effect of variable nutrient injections from extra-tropical water masses on the equatorial Pacific upwelling waters using benthic and planktonic foraminiferal carbon isotopes ($\delta^{13}\text{C}$). In combination with published records of neodymium isotopes (ϵ_{Nd}) and foraminiferal $\delta^{13}\text{C}$ values from the subarctic Pacific, the eastern North Pacific, the eastern tropical North Pacific as well as the southeast and southwest Pacific, this thesis aims to improve our knowledge of end-member contributions on EqPIW during the last two glacial-interglacial cycles, focusing in at higher resolution during Marine Isotope Stage (MIS) 2.

The results of this thesis are presented in three manuscripts. The first manuscript examines foraminiferal calcification depths in the western equatorial Pacific using living planktonic foraminifera in combination with foraminiferal abundances. Despite the relatively deep thermocline in the Western Pacific Warm Pool (WPWP), the relative order of the five investigated species was

comparable to other ocean basins. However, absolute ACDs differed due to the local hydrography in the WPWP. Surface mixed layer dwellers *Globigerinoides ruber* and *Globigerinoides sacculifer* were apparent at ~95 m and ~115 m water depth, and were found in low abundances during the sampling time. The comparatively deep thermocline between 130 – 230 m below sea level subsequently led to relatively deep calcification depths of *Neogloboquadrina dutertrei* and *Pulleniatina obliquiloculata*. Hence, both species occupy a depth habitat towards the top, and within, the thermocline. One of our major findings was that the planktonic species *Globorotaloides hexagonus* was found to occupy a deep habitat (~450 m water depth) within the Pacific. This sub-thermocline species seems to favour cool, nutrient-rich water masses and was shown to be a suitable archive for tracing nutrient-inflow of high latitude intermediate water masses on equatorial Pacific sub-thermocline.

The second and third manuscripts deal with the ventilation of Glacial North Pacific Intermediate Water (GNPIW) and its influence on the EqPIW during the past 60 ka (*Manuscript 2*) and during the last two glacial-interglacial cycles (*Manuscript 3*). It was shown that $\delta^{13}\text{C}$ records from the Bering Sea (as an indicator for GNPIW), the eastern tropical North Pacific and the EqPIW (measured on *G. hexagonus*) exhibit a similar temporal evolution during MIS 2. In addition, the absolute ϵ_{Nd} signatures from the Bering Sea and the eastern North Pacific are similar during this time period. The $\delta^{13}\text{C}$ difference between the equatorial record and northern and southern signatures, respectively, was calculated to infer the relative change of high latitude intermediate water contribution on equatorial sub-thermocline nutrient concentrations. Most interestingly, in times when the $\delta^{13}\text{C}$ differences between the EqPIW record and two Southern Ocean cores are greatest (late MIS 2 and MIS 6), the difference in $\delta^{13}\text{C}$ between the North Pacific and EEP is smallest. These results indicate increased GNPIW ventilation during glacials that spreads southward towards the eastern tropical North Pacific. During peak glacials the southward expansion of GNPIW was at a maximum and extended into the equatorial Pacific. Together with newly published evidence for a shallower penetration of relatively nutrient-depleted SOIW during glacials, these results point towards repeated episodes of reduced southern-sourced nutrient-injections into EqPIW during peak glacials. In contrast, the enhanced ventilation of nutrient-elevated GNPIW resulted in a comparatively increased nutrient contribution to the EqPIW. This intensified GNPIW nutrient-inflow possibly relaxed the nutrient limitation in the EEP, stimulating primary productivity in the EEP during peak MIS 2. As a consequence, the invigorated glacial biological pump would have sequestered more carbon dioxide (CO_2) from the atmosphere into the ocean. And thus, in summary, this thesis has contributed important new insights into the role of the dynamics of the EEP in driving the glacial reduction in atmospheric CO_2 concentrations.

Kurzfassung

Der äquatoriale Pazifik verbindet die Nord- und Südhemisphäre mittel atmosphärischer und ozeanischer Zirkulation und ermöglicht somit die Erforschung der Klimaschwankungen der Erde. Das heutige äquatoriale Pazifische Zwischenwasser (EqPIW) wird gespeist aus drei Ursprungswassermassen: aus dem Südozeanischen Zwischenwasser (SOIW), dem Pazifischen Tiefenwasser (PDW) und zu sehr geringen Anteilen aus dem Nordpazifischen Zwischenwasser (NPIW). Der geringe Anteil an Kieselsäure im SOIW, im Vergleich zu anderen Nährstoffen, ist maßgeblich für die heutige geringe Primärproduktivität von kieseligem Phytoplankton im östlichen äquatorialen Pazifik (EEP) verantwortlich. Eine erhöhte Primärproduktion im letzten Glazial wird häufig mit einer erhöhten Zufuhr von SOIW in das äquatoriale Strömungssystem erklärt. Allerdings wird in der Literatur intensiv diskutiert, ob SOIW überhaupt in der Lage war die glaziale Produktivität am Äquator zu stimulieren, da Nährstoffe während des Glazials eher im Südozean gebunden waren. Darüber hinaus weisen neue Studien darauf hin, dass sich die laterale und vertikale Ausdehnung von SOIW als auch von NPIW während der Glaziale verändert hat. Die Auswirkung dieser veränderten Zwischenwassermassen auf das äquatoriale Strömungssystem ist bis heute jedoch unklar.

Rekonstruktionen der oberen Wassersäule basieren oftmals auf Analysen an planktischen Foraminiferengehäusen. Unterschiedliche Arten leben und kalzifizieren in bestimmten Wassertiefen und eignen sich daher ideal zur Bestimmung vergangener Klimabedingungen. Es hat sich jedoch herausgestellt, dass sich die scheinbaren Kalzifizierungstiefen (ACDs) der Foraminiferenarten regional unterscheiden können. Es existiert jedoch bis heute keine ACD Bestimmungen aus Multinetzdaten aus dem äquatorialen Pazifik. Diese Dissertation bestimmt die ACDs verschiedener Foraminiferenarten, um eine Art zu ermitteln, die den Nährstoffeintrag aus den Zwischenwassermassen der hohen Breiten aufzeigen kann. Diese Art wurde anschließend verwendet, um den Effekt variabler Nährstoffzufuhr aus unterschiedlichen Ursprungswassermassen auf den äquatorialen Pazifik mittels benthischer und planktischer Kohlenstoffisotope ($\delta^{13}\text{C}$) zu rekonstruieren. Die gemessenen $\delta^{13}\text{C}$ Werte werden mit bereits publizierten $\delta^{13}\text{C}$ Werten und Neodym-Isotopendaten (ϵ_{Nd}), welche an Foraminiferen aus Sedimentkernen vom subarktischen Pazifik, dem östlichen Nordpazifik, dem östlichen tropischen Nordpazifik sowie dem südöstlichen und südwestlichen Pazifik gemessen wurden, kombiniert. Letztendlich zielt diese Dissertation darauf ab, das Wissen über die Quellen und Steuerungsmechanismen der Nährstoffzufuhr im EqPIW während der letzten zwei Glazial-Interglazialzyklen und in höherer Auflösung während des Marinen Isotopenstadiums (MIS) 2 zu verbessern.

Die Ergebnisse dieser Arbeit werden in drei Manuskripten vorgestellt. Das erste Manuskript befasst sich mit der Proxygenerierung und der daraus abgeleiteten ACDs planktischer Foraminiferen im westlichen äquatorialen Pazifik anhand fünf lebender planktischer Foraminiferenarten in Kombination mit Häufigkeitsverteilungen von Foraminiferenarten. Trotz der relativ tiefen Thermokline im Westpazifischen Warmwasserpools (WPWP) glich die relative Abfolge der fünf Arten derer aus anderen Ozeanen. Die absoluten ACDs unterschieden sich jedoch auf Grund der lokalen Hydrographie im WPWP. Dabei zeigen die oberflächennahen Arten *Globigerinoides ruber* und *Globigerinoides sacculifer* ACDs um jeweils ~95 m und ~115 m an, waren aber in nur geringen Häufigkeiten während der Probennahme vorhanden. Die verhältnismäßig tiefe Thermokline zwischen 130 – 230 m führte zu entsprechend tiefen ACDs von *Neogloboquadrina dutertrei* und *Pulleniatina obliquiloculata* am oberen Rand und innerhalb der Thermokline. Bedeutend war der Fund der im Pazifik tiefliebenden (~450 m) planktischen Art *Globorotaloides hexagonus*. Diese sub-thermokline Art kalzifiziert augenscheinlich in kühlen, nährstoff-reichem Wassermassen und stellte sich damit als ein verlässlicher Proxy zur Rekonstruktion von Nährstoffkonzentrationen im sub-thermoklinen Bereich heraus.

Das zweite und dritte Manuskript beschäftigen sich mit der Ventilation des Glazialen Nordpazifischen Zwischenwassers (GNPIW) und dessen Einfluss auf das EqPIW während der letzten 60 ka (*Manuskript 2*) und der letzten zwei Glazial-Interglazialzyklen (*Manuskript 3*). Es konnte gezeigt werden, dass $\delta^{13}\text{C}$ Datensätze aus der Bering See (als ein Anzeiger für GNPIW), dem östlichen tropischen Nordpazifik und dem EqPIW (gemessen an *G. hexagonus*) während MIS 2 einen ähnlichen zeitlichen Verlauf nehmen. Weiterhin wurde hervorgehoben, dass sich die absoluten ϵ_{Nd} Signaturen aus der Bering See und dem östlichen Nordpazifik in der gleichen Zeit kaum unterscheiden. Die $\delta^{13}\text{C}$ Differenz zwischen dem EqPIW und dem Südozean sowie Nordpazifik wurde berechnet um Rückschlüsse über die relativen Änderungen in den Steuerungsmechanismen zu schließen. Auffallend war, dass zu Zeiten in denen der $\delta^{13}\text{C}$ Unterschied zwischen der äquatoriale sub-Thermokline und dem Südozean am ausgeprägtesten war (spätes MIS 2 und MIS 6), die $\delta^{13}\text{C}$ Differenz zwischen dem Nordpazifik und dem EEP am geringsten war. Diese Ergebnisse zeigen somit, dass es während der Glaziale zu einer verstärkten Ventilation des GNPIW gekommen ist, die sich bis in den östlichen tropischen Nordpazifik erstreckte. Sie erreichte ihren Höhepunkt mit dem Erreichen des Äquators während der Hochglaziale. Im Zusammenhang mit neuen Studien, die auf eine Verflachung des relativ nährstoff-abgereicherten SOIW während der Glaziale hinweisen, zeigen die Ergebnisse dieser Dissertation eine wiederholt abnehmende Nährstoffzufuhr von südlichen Wassermassen während der Hochglaziale. Dahingehend schien die erhöhte Ventilation von GNPIW zu einer vergleichsweise gesteigerten Nährstoffzufuhr in das EqPIW zu führen. Dies wiederum hob vermutlich die Nährstofflimitierung im EEP auf und könnte die erhöhte Produktivität im EEP während des späten MIS 2 mit erklären. Als Konsequenz darauf, würde die gestärkte biologische Pumpe mehr Kohlenstoffdioxid (CO_2) aus der Atmosphäre in den Ozean sequestrieren. Letztendlich tragen die Ergebnisse dieser Dissertation somit zu den laufenden Diskussionen der abnehmenden glazialen CO_2 Konzentrationen bei.

1. Introduction

1.1 General introduction

The Earth's climate system is strongly mediated by the complex interaction of ocean, atmosphere and biosphere. Understanding the climate forcing processes, the feedback mechanisms and the teleconnections of natural climate variability are one of the main motives of (paleo)climate research. Since the discovery of glacial-interglacial variations in atmospheric carbon dioxide (CO₂) concentrations, detected in Antarctic ice cores bubbles [*Petit et al.*, 1999; *Lüthi et al.*, 2008], scientists have tried to disentangle the causes of these reoccurring fluctuations. It has been suggested that the 80 – 100 ppm range of atmospheric CO₂ concentrations between glacial and interglacial periods is attributed to a combination of physical and biogeochemical processes that among others regulate the (deep) ocean carbon reservoir [*Sarmiento and Toggweiler*, 1984; *Siegenthaler and Wenk*, 1984; *Abelmann et al.*, 2006; *Toggweiler et al.*, 2006; *Ronge et al.*, 2016]. The deep ocean contains about 60 times more carbon than the atmosphere [*Falkowski et al.*, 2000]. Thus, changes in carbon storage in the ocean interior are likely the main driver for atmospheric CO₂ fluctuations [*Sigman and Boyle*, 2000; *Toggweiler et al.*, 2006; *Sigman et al.*, 2010; *Hendry and Brzezinski*, 2014].

The Southern Ocean acts as an important exchange area of water masses as it connects the world's major ocean basins [*Talley*, 2013]. In this area, upwelling water masses from the ocean interior containing older CO₂ mix with other water masses and transform into newly formed intermediate, deep and abyssal waters that are exported to the rest of the global ocean (Figure 1.1) [*Orsi et al.*, 1999; *Sarmiento et al.*, 2004]. The Southern Ocean Intermediate Water (SOIW) [after *Pena et al.*, 2013], the largest global intermediate water mass, is subducted ('thermocline ventilation') and transported equatorward into tropical regions where they eventually upwell [*Liu and Yang*, 2003]. Thereby, changes in the SOIW composition influence both the physical (e.g. by temperature changes) and the chemical (e.g. nutrient composition) properties of the tropical thermocline and intermediate waters [*Kessler*, 2006].

Over the last decades, the role of the tropics within the climate system has been increasingly explored and seems to be more important than previously expected [*Duplessy et al.*, 1988; *Herguera et al.*, 1992; *Spero and Lea*, 2002; *Pena et al.*, 2008; *Pichevin et al.*, 2009; *Martínez-Botí et al.*, 2015]. The Western Pacific Warm Pool (WPWP) with its deep thermocline (~150 – 250 m in the centre [*Locarnini et al.*, 2013]) is one of the major sources of heat and moisture transfer from low to high latitudes. Changes in surface and sub-surface temperatures connected to variations

Figure 1.1. Modern global ocean overturning circulation schema from a Southern Ocean perspective [figure taken from *Talley, 2013*].

in the depth of the thermocline along the equator and a simultaneous shift of the wind systems (the combined effect was termed El Niño Southern Oscillation, ENSO) does not only affect regional fauna and precipitation, but also global climate through strong inter-hemispheric, extra-tropical and cross-basin connections [*Collins et al., 2010; NOAA 2016*]. Over longer timescales, changes in the strength and variability of the WPWP affect the east-west temperature gradient and is thus responsible for past ENSO variability [*Ford et al., 2015*]. In addition, variations in nutrient utilization revealed by silicon and nitrogen isotopes [*Pichevin et al., 2009; Dubois and Kienast, 2011*] as well as fluctuations in thorium-normalized organic carbon fluxes [*Kienast et al., 2007*] indicate that equatorial productivity varied over glacial-interglacial timescales. The proposed invigorated biological pump in the Eastern Equatorial Pacific (EEP) during glacial boundary conditions [*Pichevin et al., 2009*] was attributed to a shift in the nutrient composition of equatorial upper-ocean waters due to variations in the nutrient injection of its end-member sources [*Loubere et al., 2003; Robinson et al., 2009; Dubois et al., 2011; Hendry and Brzezinski, 2014*]. As the EEP acts as one of the largest CO₂ sources on Earth today [*Takahashi et al., 2009*], a change in the nutrient concentration and an associated shift in productivity would have large repercussions for the atmospheric CO₂ budget. Hence, the equatorial Pacific is an important region for studying long-term environmental changes on both regional and global scales.

1.2 Modern oceanographic setting

The equatorial Pacific is characterized by a complex and highly dynamic current system. The westward flowing North Equatorial Current (NEC) and the South Equatorial Current (SEC) are both wind-driven surface currents, which respond quickly to variations in the wind field. The inter-hemispheric differences in the distribution of landmass and ocean area lead to stronger southern hemispheric wind field component and as a result, the SEC extends from 5°N to 25°S, whereas the NEC is strongest at ~15°N (Figure 1.2a) [Tomczak and Godfrey, 2005; Kessler, 2006]. Around the Philippines, the NEC divides into a northern branch (Kuroshio Current, KC) and a southern branch, which, in turn, feeds the eastward flowing North Equatorial Counter Current (NECC). The NECC, centred at 5°N, is also partly fed by the northern extension of the SEC during the southwest monsoon [Tomczak and Godfrey, 2005].

Despite the intensive surface currents, the most prominent current in the equatorial Pacific is the eastward-directed Equatorial Under Current (EUC) and the northern and southern subsurface countercurrents (NSCC and SSCC, respectively; also termed Tsuchiya Jets after Tsuchiya, [1972]) [Johnson and Moore, 1997; Rowe et al., 2000]. The EUC with a maximum width of 500 km extends from 40 to 280 m water depth with its peak velocity at ~200 m [Wyrski and Kilonski, 1984; Johnson et al., 2002; Tomczak and Godfrey, 2005; Grenier et al., 2011]. As the EUC flows eastward across the equatorial Pacific its upper branch shoals parallel with the thermocline providing nutrients to the euphotic zone, stimulating primary productivity [Dugdale et al., 2002; Ryan et al., 2006]. The lower branch of the EUC does not upwell along the equator, but as it travels across the equator it receives nutrients from the Equatorial Pacific Intermediate Water (EqPIW) and provides nutrients to the upper EUC by diapycnal mixing [Dugdale et al., 2002; Qu et al., 2009; Bostock et al., 2010; Rafter and Sigman, 2015]. Nutrients within the EUC and the underlying EqPIW primarily originate in the extra-tropical high-nutrient low-chlorophyll (HNLC) regions [Johnson et al., 2002; Goodman et al., 2005; Qu et al., 2009; Grenier et al., 2011]. To date, the EUC and EqPIW are mainly fed by nutrient-rich Pacific Deep Water (PDW) and SOIW and only a minor proportion can be attributed to North Pacific Intermediate Water (NPIW) (Figure 1.2b) [Goodman et al., 2005; Tomczak and Godfrey, 2005; Bostock et al., 2010].

PDW is formed via the return flow of Circumpolar Deep Water (CDW) and Antarctic Bottom Water (AABW). CDW and AABW are formed primarily within the Antarctic Circumpolar Current and move slowly from the Southern Ocean towards the North Pacific. On its way, remineralisation of organic material and continuous biological export production from above leads to decreasing oxygen concentrations and nutrient accumulation. As a result, PDW is the oldest, most nutrient- and CO₂-enriched water mass in global ocean that occupies a depth range of 1500 – 3300 m [Tomczak and Godfrey, 2005; Talley, 2008].

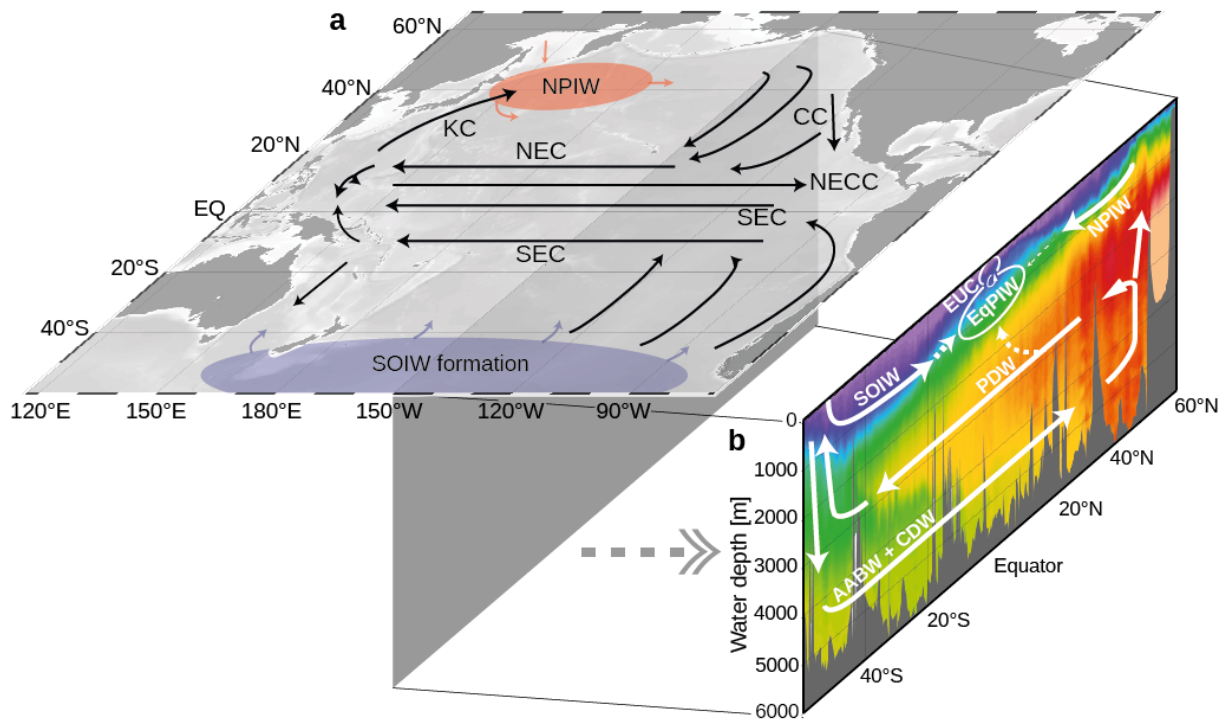

Figure 1.2. Map of the Pacific Ocean with major currents and water masses [after *Tchernia*, 1980; *Tomczak and Godfrey*, 2005; *Kessler*, 2006; *Bostock et al.*, 2010]. a: Surface water currents with formation region of Southern Ocean Intermediate Water (SOIW) and North Pacific Intermediate Water (NPIW). CC = California Current; KC = Kuroshio Current; NEC = North Equatorial Current; NECC = North Equatorial Counter Current; SEC = South Equatorial Current. b: Meridional depth transect of silicic acid concentration with major intermediate and deep currents overlain: EUC = Equatorial Undercurrent, EqPIW = Equatorial Pacific Intermediate Water, NPIW, SOIW, PDW = Pacific Deep Water, AABW = Antarctic Bottom Water, CDW = Circumpolar Deep Water. Colour shading shows silicic acid concentration with red indicating high concentrations and blue colours low silicic acid concentrations. Map and transect were generated using Ocean Data View [*Schlitzer*, 2015] with GLODAP Bottle Data [*Key et al.*, 2004].

SOIW comprises Subantarctic Mode Water (SAMW) and Antarctic Intermediate Water (AAIW) [after *Pena et al.*, 2013]. As SAMW travels within the Antarctic Circumpolar Current around the Antarctic continent it cools and freshens through deep winter mixing and isopycnal exchange along and across the Subantarctic Front [*McCartney*, 1977; *Bostock et al.*, 2013]. The densest SAMW near the Polar Front forms AAIW, which is characterized by a prominent salinity minimum (34.4 – 34.5) and an average potential density of $27.1 \sigma_\theta$ [*McCartney*, 1977; *Bostock et al.*, 2010; 2013]. Different formation areas of AAIW exist but the majority is formed in the southeast Pacific Ocean, off southern Chile [*Sallée et al.*, 2010; *Bostock et al.*, 2013]. Diatom blooms in the formation regions of SOIW remove silicic acid ($\text{Si}(\text{OH})_4$) out of the surface waters and as a result, SOIW contains depleted silicon to nitrogen ratios [*Sarmiento et al.*, 2004; *Hendry and Brzezinski*, 2014]. The relatively low-silicon SOIW is then subducted along an isopycnal surface between 300 and 1300 m [*Sloyan and Rintoul*, 2001; *Bostock et al.*, 2013] and seems to follow the wind-driven

subtropical gyre water circulation equatorwards before feeding into the low-latitude equatorial thermocline and intermediate waters [Tomczak and Godfrey, 2005]. This has the effect that, although approximately two-thirds of EUC waters are supplied by SOIW today [Goodman *et al.*, 2005; Qu *et al.*, 2009], SOIW contributes about half of the nitrate supply and only roughly 30 % of the total modern equatorial Si(OH)₄ supply [Dugdale *et al.*, 2002; Sarmiento *et al.*, 2004].

Today, NPIW only contributes insignificantly to EqPIW (Figure 1.2b). In contrast to SOIW, nutrient depletion by biological productivity is relatively limited in NPIW as it is never exposed to the surface and consequently, nutrient levels remain high [Talley, 1991; Sarmiento *et al.*, 2004]. A mixing of different water masses in the northwest Pacific with the major contribution of Okhotsk Sea Intermediate Water (OSIW) forms NPIW. OSIW, in turn, is formed in coastal polynyas during wintertime sea-ice formation within the Sea of Okhotsk [Talley, 1993; Shcherbina *et al.*, 2003]. NPIW spreads out at 300 – 800 m water depth and is characterized by a salinity minimum (33.9 – 34.1) with low oxygen concentrations (0 – 150 μmol/kg) and an average potential density of 26.8 σ_θ [Dickson *et al.*, 2000; Bostock *et al.*, 2010]. Although, the lateral extent of NPIW is restricted to 15 – 20°N today, the influence NPIW extends to the equatorial Pacific through the Celebes Sea, where it accounts for ~70 % of the modern Si(OH)₄ supply [Sarmiento *et al.*, 2004; Bostock *et al.*, 2010].

1.2.1 Western Pacific Warm Pool versus Pacific Equatorial Divergence

The equatorial Pacific is divided into two distinct biogeochemical provinces: the WPWP and the contrasting EEP with offshore equatorial upwelling (also termed Pacific Equatorial Divergence, PEqD) (Figure 1.3a). The WPWP is the largest warm water body on Earth. The surface layer is characterised by temperatures consistently higher than 28°C, low salinities (<35) and relatively low nutrient concentrations (<0.1 μM NO₃⁻; <0.2 μM PO₄³⁻) [Yan *et al.*, 1992; Blanchot *et al.*, 2001; Rafter and Sigman, 2015]. The pycnocline, which is associated with the deep thermocline, separates oligotrophic surface waters from nutrient-enriched sub-surface water masses [Herbland and Voituriez, 1979; Mackey *et al.*, 1995; Radenac and Rodier, 1996]. The equatorial thermocline shoals from the west to the east Pacific, reaching depths as shallow as 30 m in the EEP (Figure 1.3b) [Locarnini *et al.*, 2013]. The shoaled thermocline in the eastern Pacific results in the PEqD being characterized by lower temperatures (<28°C), higher salinities (>35) and elevated macronutrients levels (3 – 4 μM NO₃⁻; 0.4 – 0.5 μM PO₄³⁻) [Blanchot *et al.*, 2001; Le Borgne *et al.*, 2002]. Although chlorophyll-a concentrations are higher in the PEqD compared to the WPWP, primary productivity by siliceous phytoplankton is hindered in the PEqD due to the limitation of Si(OH)₄ and iron [Broecker and Peng, 1982; Dugdale *et al.*, 2002; Sarmiento *et al.*, 2004; Ryan *et al.*, 2006]. This makes the PEqD (in particular the EEP) one of the largest HNLC regions of the world [Minas *et al.*, 1986]. As a consequence of the low productivity, the EEP acts as the main global marine source for atmospheric CO₂ today [Takahashi *et al.*, 2009].

1.0 INTRODUCTION

Another important feature of the equatorial Pacific is the interannual instability in the coupled ocean-atmosphere system known as ENSO. On timescales between two to seven years the EEP experiences anomalously warm (El Niño) and cold (La Niña) conditions, and the opposite in the WPWP. These swings in temperature are associated with changes in the depth of the thermocline and consequently with variations in the availability of nutrients in the photic zone [Le Borgne *et al.*, 2002]. Through changes in primary productivity, ENSO is expected to have large repercussions for global atmospheric CO₂ concentrations and the global carbon budget [Feely *et al.*, 2002]. Additionally, during ENSO, the strength of the trade winds and the position of the atmospheric convection influence the hydrography of the equatorial Pacific [Collins *et al.*, 2010]. Changes in the atmospheric convection affects the upwelling of water masses along the equator and thereby, the zonal extension of the WPWP and PEqD [Le Borgne *et al.*, 2002].

Figure 1.3. Annual temperatures and nitrate concentrations in the equatorial Pacific. a: annual Sea-Surface Temperature (SST) map with the Western Pacific Warm Pool (WPWP), the Pacific Equatorial Divergence (PEqD) and the Eastern Equatorial Pacific (EEP). b: zonal annual nitrate concentrations overlaid by annual temperature contours (white) along the equator showing the higher nitrate concentration in subsurface waters of the EEP compared to the WPWP concurrent with the shoaling of the thermocline. Surface map and transect were generated using Ocean Data View [Schlitzer, 2015] with data of the World Ocean Atlas 2013 [a, Locarnini *et al.*, 2013] and GLODAP Bottle Data [b, Key *et al.*, 2004].

1.3 Relevant (paleoceanographic) research related to this thesis

Information regarding past ocean and climate changes can be decrypted using paleoceanographic proxies. A commonly used archive to measure the of desired but unobservable variables such as temperature, salinity and surface water CO₂ concentrations, are carbonate shells of planktonic foraminifera, a group of cosmopolitan free-floating marine protozoa. Foraminifera live vertically dispersed in the upper ocean water column, with different species dwelling in distinct water masses. It should be noted that for precise interpretation of paleo-data from foraminifera, it is crucial to know the calcification depth of the analysed foraminiferal species as precisely as possible. Planktonic foraminifera are known to migrate within the water column during their ontogeny [Hemleben and Bijma, 1994]. Consequently, the reconstructed habitat depth using geochemical signals will always represent an integrated signal across the entire water depth range and ontogeny of the species and should therefore be referred to as the Apparent Calcification Depth (ACD). Information about foraminiferal ACDs from the equatorial Pacific are limited. Previous studies from the equatorial Pacific rather focussed on foraminiferal fluxes [Thunell and Honjo, 1981; Fairbanks et al., 1982; Thunell et al., 1983; Kawahata et al., 2002; Yamasaki et al., 2008]. The few studies reconstructing ACDs have either concentrated on the reconstruction of past oceanic conditions with known ACDs from other ocean basins [Wara et al., 2005; Russon et al., 2010], or used surface sediments from the central or EEP [Faul et al., 2000; Lynch-Stieglitz et al., 2015; Nürnberg et al., 2015]. However, foraminiferal ACDs have been shown to differ regionally [Faul et al., 2000; Steph et al., 2009]. This is especially true for sub-surface and thermocline species such as *Neogloboquadrina dutertrei*, as the thermocline varies substantially in a highly dynamic system like the EEP [Loubere, 2001; Nürnberg et al., 2015]. The use of ACDs reconstructed from other ocean basins to target specific water masses is therefore risky and highlights the need for a precise ACD estimation from the equatorial Pacific.

Over the last half a century, it has been revealed that carbon isotope ($\delta^{13}\text{C}$) values of foraminifera can be used to reconstruct past ocean circulation and nutrient changes [Shackleton, 1974; Duplessy et al., 1984; Zahn et al., 1991; Curry and Oppo, 2005; Bostock et al., 2010; Knudson and Ravelo, 2015a]. However, due to a variety of factors (see Chapter 1.4.2) foraminiferal $\delta^{13}\text{C}$ can deviate from the total dissolved inorganic carbon of ambient seawater ($\delta^{13}\text{C}_{\text{DIC}}$), which might lead to distorted interpretations of past nutrient conditions [Oppo and Fairbanks, 1989; Spero et al., 1991; Kroon and Darling, 1995; Birch et al. 2013]. Consequently, a possible foraminiferal $\delta^{13}\text{C}$ -disequilibrium should be considered when interpreting paleo-data.

Reconstructing past ocean dynamics in the equatorial Pacific is important for regional and global climate, as the EEP is the most important source for marine CO₂ release into the atmosphere under modern conditions [Takahashi et al., 2009]. The release of CO₂ from the surface ocean in regions of upwelling is counteracted by carbon fixation of siliceous phytoplankton [Dugdale and Wilkerson, 1998]. However, the productivity of these biogenic organisms in the EEP is

hindered by the low availability of Si(OH)_4 and iron today [Broecker and Peng, 1982; Dugdale et al., 2002; Sarmiento et al., 2004; Ryan et al., 2006]. The main contributor to equatorial thermocline waters, the SOIW is characterized by high nitrate but low Si(OH)_4 concentrations [Sarmiento et al., 2004]. During the Last Glacial Maximum (LGM), an enhanced productivity in the EEP suggests that the Si(OH)_4 limitation was overcome, requiring the supply of at least three times more Si(OH)_4 to the system [Pichevin et al., 2009]. Nevertheless, the source of this Si(OH)_4 remains enigmatic. On the one hand, it has been suggested that a higher contribution of southern-sourced waters towards the equatorial Pacific thermocline resulted in higher nutrient concentrations [Pena et al., 2008]. Supporting evidence for a greater influence of southern-source waters in the Pacific comes from an authigenic mineral study from the Chilean margin that reports higher oxygen concentrations related to an enhanced production of SOIW during glacials [Muratli et al., 2010]. In addition, a neodymium isotope (ϵ_{Nd}) record [Pena et al., 2013], and shallow and deep-water radiocarbon activity ($\Delta^{14}\text{C}$) reconstructions in the EEP [de la Fuente et al., 2015] suggest that relatively old, deep-southern sourced water masses upwell at the equator during glacial boundary conditions. On the other hand, a recent $\delta^{13}\text{C}$ and oxygen isotope ($\delta^{18}\text{O}$) reconstruction combined with modelling results from the southwest Pacific argue for a decrease in the vertical extent of SOIW during glacial times [Ronge et al., 2015]. This reinforced the interpretation from previous stable isotope reconstructions from the southwest Pacific that proposed a reduced production of SOIW under glacial conditions [Pahnke and Zahn, 2005] for at least 400 ka [Elmore et al., 2015]. In addition to these isotope reconstructions, there is growing debate over whether SOIW was capable of stimulating productivity at the equatorial Pacific. Recent silicon and nitrogen isotope reconstructions argue for a “nutrient-trapping” in the Southern Ocean leaving the northward penetrating intermediate water depleted in nutrients under glacial conditions [Hendry and Brzezinski, 2014; Robinson et al., 2014; Rousseau et al., 2016].

In the North Pacific, a ϵ_{Nd} record and foraminiferal isotope studies suggest a shift in the formation region of Glacial North Pacific Intermediate Water (GNPIW) from mainly the Sea of Okhotsk towards the northwest Pacific during glacial boundary conditions [Horikawa et al., 2010; Rella et al., 2012; Max et al., 2014]. Simultaneously, a variety of $\delta^{13}\text{C}$ records propose an increased formation and strengthened mid-depth circulation (1000 – 1500 m water depth) in the North Pacific during the last glacial maximum (LGM) [Duplessy et al., 1988; Herguera et al., 1992; Keigwin, 1998; Matsumoto et al., 2002a; Cook et al., 2016]. A recent endobenthic foraminiferal $\delta^{13}\text{C}$ study demonstrates that this increased GNPIW formation occurred during glacials at least since the mid-Pleistocene [Knudson and Ravelo, 2015a]. The enhanced GNPIW might have expanded further south along the California margin [Stott et al., 2000] and the Eastern Tropical North Pacific (ETNP) [Leduc et al., 2010]. In the EEP, a very recent Pacific ϵ_{Nd} data compilation revealed a substantial LGM to Holocene shift in ϵ_{Nd} values that can only be explained by a higher contribution from northern-sourced waters [Hu et al., 2016]. However, it has not yet been revealed how the proposed diminished SOIW and enhanced GNPIW convection might have influ-

enced the nutrient distribution and biological productivity beyond the northern high latitudes during the LGM and further back in time.

1.4 Planktonic foraminifera as paleo-proxies

1.4.1 Brief overview on planktonic foraminiferal ecology

Planktonic foraminifera are exclusively marine eukaryotic protozoans that are globally distributed in the upper water column of the world's ocean [Hemleben *et al.*, 1989]. A prominent feature is the formation of a calcium carbonate shell (= test), on which modern taxonomic classification is based on. Up to 50 extant planktonic foraminiferal species have been identified, which can be divided into spinose and non-spinose species [Schiebel and Hemleben, 2005]. Although, planktonic foraminifera are generally heterotrophic [Hemleben *et al.*, 1989], some species, in particular spinose species, possess algal symbionts. These symbionts, which are mainly dinoflagellates, produce energy through photosynthesis, which the foraminifera use to drive the calcification process [Schiebel and Hemleben, 2005].

The abundance of planktonic foraminiferal species strongly depends on environmental parameters, resulting in a species characteristic biogeographic distribution. Five major faunal provinces were determined: tropic, subtropic, transitional, subpolar and polar [Bé, 1977]. The provinciality in modern foraminifers is restricted to global climate belts and hence typically to the thermal structure of the water column [Bé and Tolderlund, 1971]. Nevertheless, other factors such as salinity, radiation for symbiont-bearing species, turbidity of the ambient water, food supply and distribution of predators determine the spatial and vertical distribution as well [Bijma *et al.*, 1990; Watkins *et al.*, 1996; Schiebel and Hemleben, 2005]. Plankton tow analysis revealed that living species are restricted to the euphotic zone and the quantity decreases with increasing water depth. Although changes in salinity play only a marginal role for the foraminiferal depth distribution directly, it affects the density structure of the water column and thereby the accumulation of nutrients in certain depths. As certain species of planktonic foraminifera are often associated with the deep chlorophyll maximum (DCM) where nutrients accumulate [Fairbanks *et al.*, 1982; Schiebel *et al.*, 2001], salinity might therefore affect foraminiferal depth distribution indirectly. Consequently, their distinct distribution is mainly controlled by the prevailing surface hydrography and each species inhabit characteristic ecological niches [Fairbanks and Wiebe, 1980; Schiebel and Hemleben, 2005].

The formation of calcium carbonate (CaCO_3) tests makes planktonic foraminifera an important carbonate producer with an average of 1.3 – 3.2 Gt CaCO_3 per year in the global ocean [Schiebel, 2002]. During their ontogeny (maturation), the majority of foraminifera migrate through the water column, whilst adding new chambers and covering and thickening the whole pre-existing test by an additional layer of calcite [Kozdon *et al.*, 2009]. Thus, the calcite records the

varying temperatures and salinity of the respective water depth. As each successive chamber is larger and heavier than the previous chamber [*Hemleben and Bijma, 1994*], the shell weight and therefore the geochemical signature of the whole shell, is determined by the last few chambers. During the final phase that is associated with gametogenesis, spinose foraminifera shed their spines, eject the symbionts and secrete a smooth veneer of calcite covering spine holes [*Hemleben et al., 1989*]. Following gametogenesis, planktonic foraminiferal tests sink to the seafloor, constituting 32 – 80 % of the total deep-marine calcite budget [*Schiebel and Hemleben, 2005*]. Due to their global distribution, their specific adaptation to environmental conditions, their good fossilization potential and continuous occurrence in the geological record since the Jurassic about 180 Ma ago [*Cifelli, 1969*], planktonic foraminifera tests are frequently used to decrypt past ecological and oceanographic conditions.

1.4.2 General influences on foraminiferal shells

Foraminiferal tests are the by far most commonly analysed carbonates for reconstructing past environmental changes such as the thermal structure of the water column, depth of thermocline, nutrient cycling, circulation changes, and ventilation changes. The application is based on the relationship between foraminiferal calcite and the ambient seawater. However, there are a number of physical, chemical and biological effects on both regional and global scales which may affect the fidelity of foraminiferal calcite to reflect ambient seawater (Figure 1.4) [*Schiebel and Hemleben, 2005*].

1.4.2.1 Stable isotopes

The incorporation of oxygen and carbon isotopes into foraminiferal calcite is affected by isotopic fractionation. Generally, isotopic fractionation is defined as “the partitioning of isotopes between two substances or two phases of the same substance with different isotope ratios” [*Hoefs, 2009*]. In this regard, a distinction is made between equilibrium isotope fractionation and non-equilibrium fractionation. Equilibrium isotope fractionation occurs usually during isotope exchange reactions, e.g. air-sea gas exchange. It involves the forward and backward isotope reaction rates among various well-mixed systems. In contrast, non-equilibrium fractionation is the result of incomplete or unidirectional processes such as kinetic isotope effects in chemical reactions, evaporation, photosynthesis and metabolic effects. This non-equilibrium reactions favour reaction of the lighter isotope compared to the heavier isotope, since light isotopes have a higher mobility [*Zeebe and Wolf-Gladrow, 2001*].

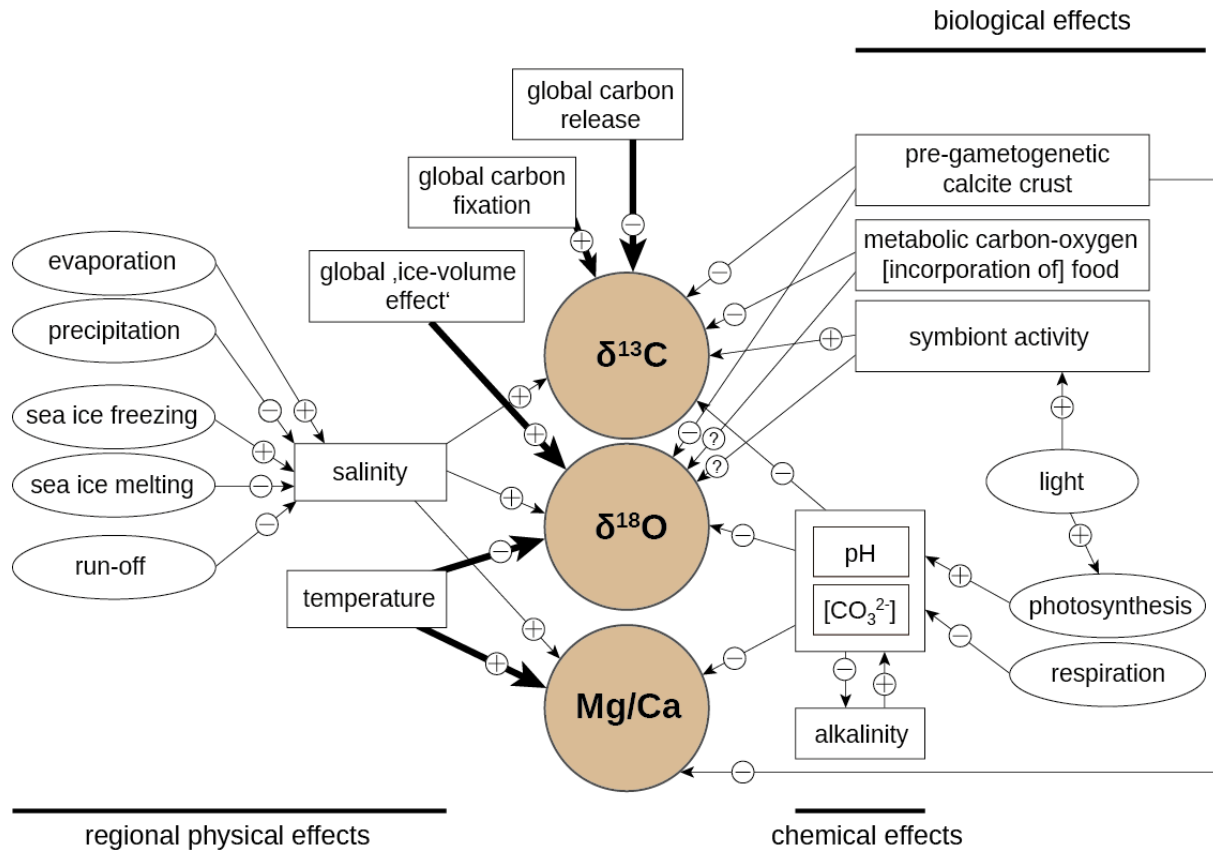

Figure 1.4. Summary of the influencing factors on the stable oxygen ($\delta^{18}\text{O}$) and carbon ($\delta^{13}\text{C}$) isotope composition as well as on the Magnesium/Calcium (Mg/Ca) ratio of planktonic foraminiferal tests. Bold arrows mark predominant effects. Positive and negative correlations are indicated by [+] and [-], respectively [modified after *Schiebel and Hemleben, 2005*].

Oxygen isotopes

The oxygen isotope composition of the foraminiferal calcite ($\delta^{18}\text{O}_{\text{calcite}}$) reflects the oxygen isotope composition of the ambient seawater ($\delta^{18}\text{O}_{\text{seawater}}$) with a temperature-dependent fractionation between ^{18}O and ^{16}O [McCrea, 1950]. In this context, at higher temperatures less ^{18}O is incorporated into the calcite shell and vice versa. Besides the dominating role of temperature, there are several processes that affect the $\delta^{18}\text{O}_{\text{seawater}}$ itself, which have implications for the $\delta^{18}\text{O}_{\text{calcite}}$. These processes include local changes due to evaporation and precipitation, input of continental freshwater, and storage of light isotopes in continental ice ("ice-volume effect") [Craig and Gordon, 1965; Dansgaard and Tauber, 1969; Siegenthaler et al., 1979]. The periodic growth and decay of continental ice caps was first described by Shackleton [1967] and is now a well-established stratigraphic tool, the so-called Marine Isotope Stages (MIS) [Emiliani, 1955]. Furthermore, some species precipitate calcite in disequilibrium from ambient $\delta^{18}\text{O}_{\text{seawater}}$ due to so-called "vital effects" [Urey et al., 1951; Wefer, 1985; Niebler et al., 1999]. These vital effects include ontogenetic effects, symbiont photosynthesis effects, respiration effects and effects of changes in the carbonate ion concentration of seawater (also referred to as pH effect) [Hemleben

et al., 1989; *Wefer and Berger*, 1991; *Spero and Lea*, 1993; *Ravelo and Fairbanks*, 1995; *Bijma et al.*, 1999; *Niebler et al.*, 1999; *Bemis et al.*, 2000; *Birch et al.*, 2013].

Since the pioneer work of *Urey* [1947], the use of $\delta^{18}\text{O}_{\text{calcite}}$ became a basic tool in paleoceanography. The $\delta^{18}\text{O}$ -paleotemperature calculations were first established and applied by *Epstein et al.* [1951], *Urey et al.* [1951], and *Emiliani* [1955]. Since then, a number of empirically-derived paleotemperature equations have been developed on both inorganically precipitated carbonates and foraminiferal calcite [*Shackleton*, 1974; *Erez and Luz*, 1983; *Kim and O'Neil*, 1997; *Bemis et al.*, 1998; *Anand et al.*, 2003; *Mulitza et al.*, 2004; *Mohtadi et al.*, 2009]. These foraminiferal-derived equations can be either generic or species-specific, and have been generated using either cultured species, plankton tow samples or living samples from the water column [*Bemis et al.*, 1998; *Ganssen and Kroon*, 2000; *Dekens et al.*, 2002; *Regenberg et al.*, 2009; *Dueñas-Bohórquez et al.*, 2011]. They all have basic similarities, but small differences among them can result in different temperature estimates when applying to the same isotope sample (Figure 1.5) [*Bemis et al.*, 1998; *King and Howard*, 2005; *Wejnert et al.*, 2013].

Another research approach is the use of paleotemperature equations to calculate the predicted theoretical inorganic calcite value ($\delta^{18}\text{O}_{\text{equilibrium}}$) that is precipitated in isotopic equilibrium with the ambient temperature and $\delta^{18}\text{O}_{\text{seawater}}$ [*Regenberg et al.*, 2009; *Steph et al.*, 2009]. The comparison of measured foraminiferal $\delta^{18}\text{O}_{\text{calcite}}$ values with predicted $\delta^{18}\text{O}_{\text{equilibrium}}$ can be used to assess the ACD of a species by integrating the entire calcification history of a specimen.

Figure 1.5. Temperature versus $\delta^{18}\text{O}_{\text{calcite}}$ minus seawater [c-w] with various published paleotemperature equations [modified after *Bemis et al.*, 1998].

Carbon isotopes

Shell formation of foraminifera is closely coupled to the $\delta^{13}\text{C}_{\text{DIC}}$ of the ambient seawater [Berger *et al.*, 1978; Spero, 1992]. Modern ocean $\delta^{13}\text{C}_{\text{DIC}}$ values typically range from -1 ‰ to +3 ‰. However, the $\delta^{13}\text{C}_{\text{DIC}}$ is neither distributed uniformly nor is it constant over time. Long-term changes involve the interaction between the atmosphere, ocean and terrestrial biosphere as well as geological reservoirs. Short-term $\delta^{13}\text{C}_{\text{DIC}}$ modulations involve (a) changes in air-sea fractionation due to thermodynamic effects, which are especially important in cold waters at high latitudes [Broecker and Maier-Reimer, 1992; Lynch-Stieglitz *et al.*, 1995; Mackensen, 2012], (b) the photosynthesis-respiration cycle [Broecker, 1982; Kroopnick, 1985; Rohling and Cook, 1999], (c) whole-ocean variations in the carbonate chemistry of seawater [Spero *et al.*, 1997], (d) advective and diffusive mixing processes during water mass circulation, and (e) changes in species habitat or ecology (especially in planktonic species).

Planktonic foraminiferal $\delta^{13}\text{C}$ usually varies between -2 ‰ and +2 ‰ [Wefer and Berger, 1991] and has been shown to be a reliable tracer for past oceanic circulation and nutrient reconstructions [Shackleton, 1974; Duplessy *et al.*, 1984; Curry *et al.*, 1988; Oppo and Fairbanks, 1990; Zahn *et al.*, 1991; Sarnthein *et al.*, 1994; Mackensen *et al.*, 2001; Bickert and Mackensen, 2004; Curry and Oppo, 2005; Bostock *et al.*, 2010; Knudson and Ravelo, 2015a]. However, it should be noted that a number of factors can result in foraminifera secreting their carbonate shell in $\delta^{13}\text{C}$ disequilibrium with ambient seawater. Such factors include algal photosynthesis [Bé *et al.*, 1982; Hemleben *et al.*, 1989], metabolic fractionation [Wefer and Berger, 1991; Kroon and Darling, 1995; Spero *et al.*, 1997], food availability [Spero *et al.*, 1991; Ortiz *et al.*, 1996], and carbonate chemistry of the seawater [Spero *et al.*, 1997; Bijma *et al.*, 1999]. These factors should be taken into account when interpreting foraminiferal $\delta^{13}\text{C}$ to reconstruct past ocean conditions.

1.4.2.2 Mg/Ca paleothermometry

Measuring the elemental composition of Magnesium (Mg) to Calcium (Ca) in foraminiferal calcite enables the reconstruction of past ocean temperatures. The substitution of Ca by the divalent cation Mg is primarily dependent on the temperature of the ambient seawater with high Mg incorporation at high temperatures and vice versa (Figure 1.6) [Blackmon and Todd, 1959; Nürnberg, 1995; Nürnberg *et al.*, 1996; Lea *et al.*, 1999]. Culture based [Nürnberg *et al.*, 1996; Lea *et al.*, 1999; Dueñas-Bohórquez *et al.*, 2009, 2011], core-top [Dekens *et al.*, 2002; Elderfield and Ganssen, 2000; Elderfield *et al.*, 2002; Regenberg *et al.*, 2009] and sediment trap [Anand *et al.*, 2003; Mohtadi *et al.*, 2009; Friedrich *et al.*, 2012] studies have developed species-specific Mg/Ca-paleotemperature equations and established the foraminiferal Mg/Ca paleothermometry as a key paleoceanographic tool for reconstructing past ocean temperatures [Nürnberg, 1995; Nürnberg *et al.*, 1996, Rosenthal *et al.*, 1997; Nürnberg *et al.*, 2000; Lea *et al.*, 2000; Stott *et al.*, 2002; Russell *et al.*, 2004; Dueñas-Bohórquez *et al.*, 2011; Rosenthal *et al.*, 2013; Steinke *et al.*, 2014; Spero *et al.*, 2015]. Other environmental factors such as salinity or seawater pH have only

a marginal influence due to the relative overpowering control of temperature on foraminiferal Mg [Lea et al., 1999; Kısakürek et al., 2008; Yu and Elderfield, 2008; Arbuszewski et al., 2010; Hönisch et al., 2013; Spero et al. 2015].

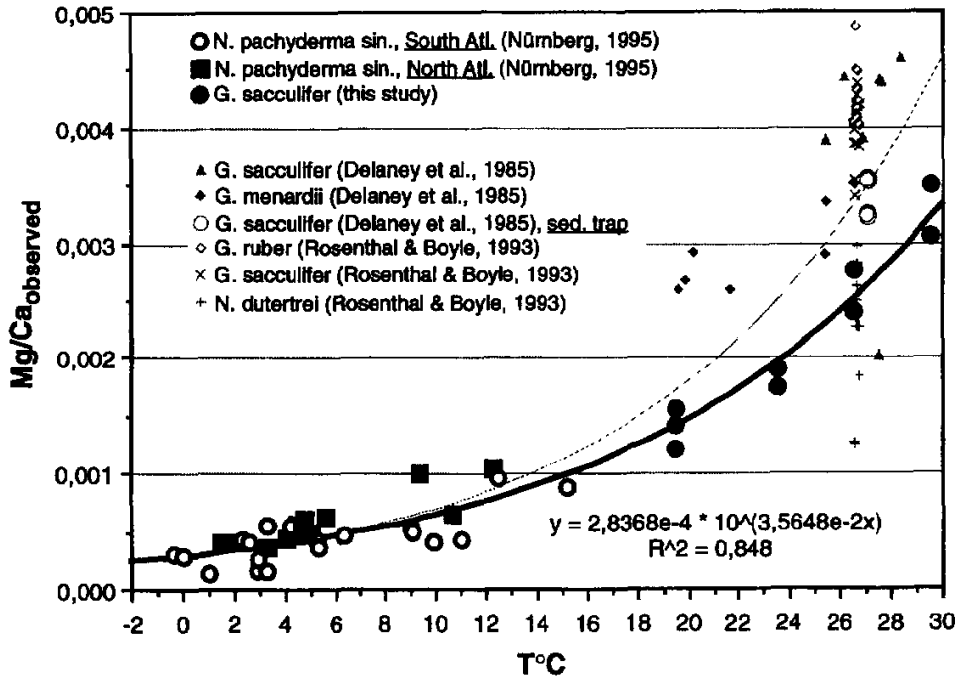

Figure 1.6. Mg/Ca ratios of various planktonic foraminifera species versus water temperature imply an exponential relationship between test chemistry and temperature [figure taken from Nürnberg et al., 1996].

1.5 Aims of the thesis

Understanding the causes and consequences of climate change on glacial-interglacial time-scales are a key goal for global climate research. The equatorial Pacific with the large WPWP and the contrasting EEP upwelling system has been long in the focus of (paleo-)climatic research, as strength and variability of both regions have large effects on global climate. Varying nutrient concentrations in the EEP might have caused changes in the primary productivity and hence, CO₂ concentrations during the last glacial cycles. However, the source for these changes remains elusive. The Southern Ocean has been a focal point in trying to determine the source of glacial-interglacial changes in the equatorial Pacific, as SOIW is the main contributor to the equatorial thermocline today. With new sediment cores available now from the Pacific sector of the Southern Ocean, there is growing debate about the SOIW influence on the equatorial upwelling system during glacials. Detailed information concerning the northern high latitudes mostly focuses on the North Atlantic, as high-resolution records from the North Pacific were relatively scarce. However, more recently, newly recovered sediment material from the Bering Sea and Sea of Okhotsk highlight substantial changes in ocean circulation in the North Pacific. This allows for the first time to compare records from the source region of SOIW and NPIW with equatorial Pacific

records to decipher changes in the relative contribution of extra-tropical intermediate waters on the nutrient distribution of equatorial water masses.

Tracing the water mass signals over time requires reliable paleoproxies. Geochemical studies on planktonic foraminifera are an established tool for paleoceanographic reconstructions, including the reconstruction of water temperatures, salinities as well as productivity and circulation changes (see *Chapter 1.3*). However, using these approaches requires a precise knowledge of the calcification depth of the foraminiferal species.

Thus, the aims of this thesis are:

1) to examine the proxy-generation of planktonic foraminifera in the WPWP and derived from it to determine regional foraminiferal ACDs in order to identify a deep-dwelling planktonic foraminifera, which can serve as a proxy for reconstructing nutrient concentrations in equatorial Pacific sub-thermocline water masses (*Chapter 3*).

2) to determine whether the relative nutrient-inflow from northern-sourced versus southern-sourced waters on tropical intermediate waters and equatorial sub-thermocline changed during the last glacial period (*Chapter 4*).

3) to identify possible implications for equatorial sub-thermocline nutrient variability and biological productivity during the last glacial period (*Chapter 4*).

4) to reconstruct the equatorial long-term variability spanning more than one glacial-interglacial cycles to decipher if the changing end-member contribution is a reoccurring signal during the Pleistocene (*Chapter 5*).

1.6 Author's contribution

Manuscript 1 (Chapter 3)

Nadine Rippert, Dirk Nürnberg, Jacek Raddatz, Edith Maier, Ed Hathorne, Jelle Bijma, and Ralf Tiedemann. *Constraining foraminiferal calcification depths in the Western Pacific Warm Pool*.

I collected water samples for stable isotope measurement from the (Conductivity-Temperature-Depth (CTD) rosette system during the research cruise SO225 on board of the German RV SONNE (November 2012 – January 2013) and helped with the multinet sampling. I performed the multinet sample treatment including the selection of foraminifera from the remaining organic material as well as the identification and counting of foraminiferal species and the subsequent selection of specific foraminifera for stable isotope analyses. Additionally, I selected

and prepared foraminiferal tests for Mg/Ca analyses, and performed the measurements via laser ablation. I wrote the entire manuscript. Dirk Nürnberg, Jacek Raddatz, Edith Maier and Ralf Tiedemann contributed to the interpretation of the data. Ed Hathorne and Jelle Bijma assisted with the preparation, performance and interpretation of the laser ablation. All co-authors reviewed the draft and contributed to the discussion. The paper is published in *Marine Micropaleontology*, doi:10.1016/j.marmicro.2016.08.004.

Manuscript 2 (Chapter 4)

Lars Max, Nadine Rippert, Lester Lembke-Jene, Isabel Cacho, Andreas Mackensen, Dirk Nürnberg, and Ralf Tiedemann. *Evidence for enhanced convection of North Pacific Intermediate Water to the low-latitude Pacific under glacial conditions.*

For this manuscript I selected the deep-dwelling foraminifera *Globorotaloides hexagonus* of sediment core ODP Site 1240 for the first 60 ka. Furthermore, I assessed the ACD of *G. hexagonus* to validate its deep calcification depth. I wrote the material section of ODP Site 1240 and the ACD determination in the methodology chapter. Additionally, I contributed to the interpretation and discussion of the manuscript during the writing process and journal review stages and edited the manuscript in each processing step. The manuscript is under review in *Paleoceanography*.

Manuscript 3 (Chapter 5)

Nadine Rippert, Lars Max, Andreas Mackensen, Isabel Cacho, Patricia Povea, and Ralf Tiedemann. *Alternating influence of northern versus southern-sourced water masses on the equatorial Pacific sub-thermocline during the past 240 ka.*

I extended the record of planktonic foraminifera *Globorotaloides hexagonus* from ODP Site 1240 for stable isotope analyses. I improved the existing age model of ODP Site 1240 by using new benthic isotope data (measured by Patricia Povea). Furthermore, for consistency, I refined previously published age models of South Pacific sediment core SO136-003/MD06-2990 [Ronge *et al.*, 2015] and Bering Sea sediment core U1342 [Knudson and Ravelo, 2015a]. I wrote the entire manuscript. Lars Max and Ralf Tiedemann contributed to the interpretation of the data. Andreas Mackensen assisted with the stable isotope analyses. Isabel Cacho helped with sampling of sediment core ODP Site 1240 and Patricia Povea provided the benthic stable isotope data of ODP Site 1240. All co-authors reviewed the draft version and contributed to the discussion. The manuscript is in preparation for *Paleoceanography*.

2. Material and Methods

This chapter describes the material and methods that I used to obtain the results shown in the manuscripts presented in *Chapters 3, 4* and *5*. Further materials and methods included in these following chapters were analysed by co-authors of the respective manuscripts and are therefore not considered in this chapter.

2.1 Study material

For this thesis, material from two study sites was analysed. First, samples from the water column of the western equatorial Pacific (Station SO225-21; 3°03.062'S, -165°03.342'W, Manihiki Plateau) [Werner *et al.*, 2013] were investigated to assess foraminiferal calcification depths. Second, sediment samples from the eastern equatorial Pacific (Ocean Drilling Program (ODP) Leg 202 Site 1240; 00°01.311'N, 86°27.758'W, 2921 m water depth) were studied to reconstruct past ocean circulation and nutrient distribution (Figure 2.1).

Figure 2.1. Map of the equatorial Pacific with CTD station SO225-21-1, multinet station (MN) SO225-21-3 as well as the location of sediment core ODP Site 1240.

2.1.1 Western equatorial Pacific

At the northernmost edge of the Manihiki Plateau in the WPWP, a multiple open/closing plankton net was used to catch foraminiferal assemblages and to analyse the geochemical signatures of foraminifera in order to determine foraminiferal calcification depths. Furthermore, a CTD profile of the water column was conducted to analyse physical and chemical properties of the water column. Both devices were used during RV SONNE cruise SO225.

2.0 MATERIAL AND METHODS

In-situ temperature, salinity and oxygen measurements of the 5170 m water column were conducted with a CTD device, which was attached at 24 bottle-rosette system á 10 L (SO225-21-1) [Werner *et al.*, 2013]. During the up-cast the bottles of the rosette were systematically closed at 15 selected depths to retrieve the relevant water samples. For each water depth, a 50 ml and a 100 ml subsample was taken and stored in glass bottles for $\delta^{13}\text{C}_{\text{DIC}}$ and $\delta^{18}\text{O}_{\text{seawater}}$ analyses, respectively. To prevent biological activity and interaction with air, the water samples for carbon isotope analysis were poisoned with 100 μl of saturated mercuric chloride (HgCl_2) solution and sealed with beeswax. Upon measurement, the samples were stored at +4°C.

The multiple open/closing plankton net (SO225-21-3) was used at the same station as the CTD [Werner *et al.*, 2013] (Figure 2.1) allowing for stratified vertical sampling of the water column. The net has a square opening of 50 x 50 cm, a 55 μm mesh size, and five net bags. The samples were taken in depths that represent the most commonly investigated upper ocean intervals in paleoceanographic research incorporating the sea surface (0 – 50 m), sub-surface (50 – 100 m), upper thermocline (100 – 200 m), lower thermocline (200 – 300 m) and sub-thermocline (300 – 500 m) as shown by the CTD cast (Figure 2.2) [e.g. Spero *et al.*, 2003; Wara *et al.*, 2005; Kiefer *et al.*, 2006; Pena *et al.*, 2008; Regenberg *et al.*, 2009; Nürnberg *et al.*, 2015]. The relatively large depth intervals were selected to capture enough material for our analyses since the area is known for low primary productivity. Immediately after collection, plankton tow samples were preserved with an Ethanol-Bengal Rose solution and stored at +4°C. In a next step, the foraminifera were wet picked, dried and counted using a reflective light microscope (Zeiss SteREO Discovery.V8). Five species (*Globigerinoides ruber*, *Globigerinoides sacculifer*, *Neogloboquadrina dutertrei*, *Pulleniatina obliquiloculata* and *Globorotaloides hexagonus*) were selected for further analysis (more details in Chapter 2.2).

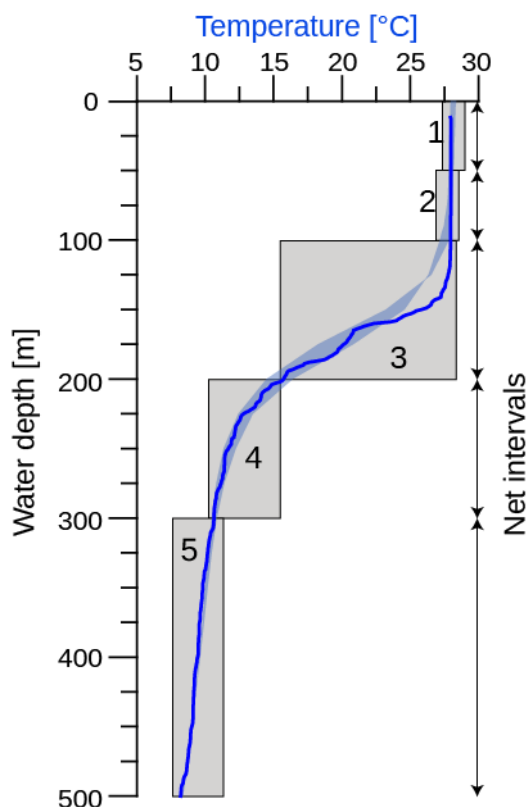

Figure 2.2. Water column temperature record of the uppermost 500 m measured at station SO225-21 (dark blue) together with the five chosen multinet-intervals. In light blue shading indicate long-term seasonal temperature variations [Locarnini *et al.*, 2013].

2.1.2 Eastern Equatorial Pacific (EEP)

Material from the EEP was recovered during ODP Leg 202 Site 1240 from the northern flank of the Carnegie Ridge in the Panama Basin (Figure 2.1) [Mix *et al.*, 2003]. A 282.9 m sediment sequence was recovered at Site 1240 consisting mainly of nanofossil ooze and diatom-nannofossil ooze and only little of siliciclastic material, mainly clay minerals [Mix *et al.*, 2003]. Furthermore, eight ash layers were present in ODP Site 1240. Within the scope of this thesis, only the first 30 m of ODP Site 1240 were investigated spanning the last 300 kyr. Sediment samples had already been washed and separated into sub-fractions at the University of Barcelona. Using a reflective light microscope (Zeiss SteREO Discovery.V8) five specimens of deep-dwelling foraminifera *G. hexagonus* were collected from the 250 – 315 μm size fraction of each selected sediment depth for $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ isotope analyses.

2.2 Applied methods

2.2.1 Foraminiferal counting

This study provides the first living foraminiferal abundance analyses from a multiple open/closing plankton net at the Manihiki Plateau. The recovered (coloured) material consisted of plankton from various size fractions (Figure 2.3). Plankton net samples were sieved over nets with a mesh size of 1000 μm and 63 μm to select foraminiferal tests more efficiently. As spinose species often tend to stuck to larger organic material, the filtered material $>1000 \mu\text{m}$ was examined for foraminiferal tests as well. From the size fraction 125 – 1000 μm intact planktonic foraminifera were wet picked collected using a binocular microscope, and dried afterwards. Foraminifera with coloured cytoplasm in the early chambers were selected, which we infer represent specimens that were collected alive or shortly after they died. This thesis primarily focuses on foraminifera $>125 \mu\text{m}$. This size fraction is well established in paleoceanographic research, in which many studies focuses on foraminifera in the size the range between 250 and 500 μm [Dekens *et al.*, 2002; Wara *et al.*, 2005; Kiefer *et al.*, 2006; Knudson and Ravelo, 2015a; Nürnberg *et al.*, 2015]. We enlarged the size fraction slightly to have broad overview over the even smaller sized foraminiferal species. Depending on the amount of material approximately 200 – 400 foraminifera were identified and selected, either in the whole sample or in aliquots. The planktonic foraminiferal taxonomy follows the work of Parker [1962], Bé [1977] and Hemleben *et al.* [1989].

Figure 2.3. Multinet sample from 0 – 50 m water depth show the various size fractions of the recovered material.

Several studies have shown that *Globigerinoides ruber* (white) exists in different morphotypes that dwell in slightly different water depths near the sea surface [e.g. Wang, 2000; Steinke et al., 2005; Kuroyanagi et al., 2008]. The determination of the morphotypes *sensu strictu* (s.s.) and *sensu lato* (s.l.) follows the concept of Wang [2000] (Figure 2.4), after which *G. ruber* s.s. has spherical chambers sitting symmetrically over previous sutures with high arched apertus and *G. ruber* s.l. corresponds to more compressed subspherical chambers with a small aperture. The morphotype *G. ruber* s.s. has been found to dwell in shallower water depths and was thus selected for the analysis. Nevertheless, due to limited amount of material, specimens of the slightly deeper dwelling *G. ruber* s.l. were also included in our dataset when necessary.

Figure 2.4. The different morphotypes of *Globigerinoides ruber*. a: morphotype *sensu strictu* (s.s) and b: *sensu lato* (s.l.) [figure modified after Wang, 2000].

For comparisons with published data, the foraminiferal density in the water column was calculated using the following formula:

$$\rho = \frac{\#}{(a * a) * b} \quad (1)$$

with ρ being the foraminiferal density, a being the multinet opening in meters and b the depth interval the respective net was hauled.

2.2.2 Stable isotope analyses

Foraminiferal stable isotope ratios ($\delta^{18}\text{O}$ and $\delta^{13}\text{C}$) were carried out at the Alfred-Wegener-Institut, Helmholtz Zentrum für Polar- und Meeresforschung (AWI), Germany, using Finnigan MAT 251 and MAT 253 isotope mass spectrometers that are coupled to automatic carbonate preparation devices Kiel II and IV, respectively. The stable isotope ratios are given in permil (δ)-notation, calibrated via international standard NBS 19 to the Vienna PeeDee Belemnite (VPDB) scale. They are determined as follows:

$$\delta_{\text{sample}} = \left[\frac{(\text{heavy isotope/light isotope})_{\text{sample}}}{(\text{heavy isotope/light isotope})_{\text{VPDB}}} - 1 \right] * 1000 \quad (2)$$

The precision of the measurements, determined over a one-year period and based on repeated analysis of an internal laboratory standard (Solnhofen limestone), is $\pm 0.06 \text{ ‰}$ and $\pm 0.08 \text{ ‰}$ (1σ) for carbon and oxygen isotopes, respectively.

The isotopic composition of seawater samples were determined on a Delta S for the $\delta^{18}\text{O}_{\text{seawater}}$ and on a Gas Bench II MAS 252 for the $\delta^{13}\text{C}_{\text{DIC}}$ at the AWI. The $\delta^{18}\text{O}_{\text{seawater}}$ values were calibrated to the Vienna standard mean ocean water (VSMOW) scale and $\delta^{13}\text{C}_{\text{DIC}}$ via the international standard NBS 19 to the VPDB scale. The precision based on an internal laboratory standard (Ocean 3 and DML for $\delta^{18}\text{O}_{\text{seawater}}$ and Solnhofen limestone for $\delta^{13}\text{C}_{\text{DIC}}$) measured over a one-year period is $\pm 0.03 \text{ ‰}$ (1σ) for $\delta^{18}\text{O}_{\text{seawater}}$ and $\pm 0.1 \text{ ‰}$ (1σ) for $\delta^{13}\text{C}_{\text{DIC}}$.

2.2.3 Determination of trace element ratios

The Mg/Ca ratios of the foraminiferal shells were obtained via laser ablation coupled to a Inductively Coupled Plasma-Mass Spectrometer (LA-ICP-MS). Compared to solution based trace element ICP-MS analyses, LA-ICP-MS requires only very little sample material and only minimal pre-treatment as surface contamination can be removed by pre-ablating samples prior to analysis. Further, it allows to obtain a large range of element concentrations in solid samples and to detect element variabilities within samples.

As many chambers as possible were measured to ensure to have sampled as much test material as possible (Figure 2.5). It has been shown that the large final chamber makes up the bulk

of solution based measurements [Hemleben and Bijma, 1994] and average element ratios determined over the whole tests, are in good agreement with published empirical calibrations on bulk foraminifera [Kunioka et al., 2006; Spero et al., 2015]. Thus, the laser ablation method is ideally suited for the trace element analyses of the multinet samples, which contain only little measurable material.

The geochemical analyses were carried out with the Excimer ArF 193 nm laser ablation system from NEW Wave ESI with a two-volume ablation cell design, coupled to an Agilent 7500cs LA-ICP-MS at GEOMAR, Helmholtz Centre for Ocean Research Kiel, Germany. A more detailed description about the settings for the laser ablation analysis is given in Chapter 3.2.3.

Figure 2.5. Foraminiferal species analysed for Mg/Ca. Holes show the penetration of the laser. White line denotes always 100 μm . a: *Globigerinoides ruber*, b: *Globigerinoides sacculifer*, c: *Neoglobobulimina dutertrei*, d: *Pulleniatina obliquiloculata* and e: *Globorotaloides hexagonus*.

2.2.3.1 Mg/Ca paleothermometry

Foraminiferal Mg/Ca ratios have become an established proxy to reconstruct past climate system changes over the last decades. The uptake of Mg into biogenic calcite shows an exponential dependency on temperature after:

$$\text{Mg/Ca} = B \cdot \exp(A \cdot T) \quad (3)$$

with the pre-exponential and exponential constants given as B and A, respectively, and T denotes the $\delta^{18}\text{O}$ calcification temperature [Nürnberg et al., 1996; Lea et al., 1999; Elderfield and Gansson, 2000; Dekens et al., 2002; Anand et al., 2003; Regenberg et al., 2009; Friedrich et al., 2012]. However, the Mg incorporation into foraminiferal tests is highly biologically mediated

[Nürnberg *et al.*, 1996; Lea *et al.*, 1999; Dueñas-Bohórquez *et al.*, 2009; 2011]. Due to these so-called “vital effects” species-specific differences in the uptake of Mg into the foraminiferal calcitic test occur. As a consequence, a large number of culture-based, sediment-trap and core-top studies have generated many different generic and species-specific paleotemperature equations that have basic similarities but also differ slightly from each other [Nürnberg *et al.*, 1996; Dekens *et al.*, 2002; Anand *et al.*, 2003; Cléroux *et al.*, 2008; Regenberg *et al.*, 2009]. These small differences might lead to different temperature estimates when applied to the same Mg/Ca ratio. Therefore, different paleotemperature equations were tested (Table S3.5.3) to find the most suitable temperature equation for the planktonic foraminifera from the multinet.

2.3 Assessment of apparent calcification depth (ACD)

The ACDs of foraminiferal species were determined both in the western equatorial Pacific as well as in the EEP. At the Manihiki Plateau two approaches were combined to assess the ACDs of five selected species with improved accuracy. First, measured $\delta^{18}\text{O}_{\text{calcite}}$ was compared to $\delta^{18}\text{O}_{\text{equilibrium}}$. To determine the $\delta^{18}\text{O}_{\text{equilibrium}}$, different paleotemperature equations [Shackleton, 1974; Kim and O’Neil, 1997; Bemis *et al.*, 1998 (*Orbulina universa* high light); Mulitza *et al.*, 2004] were used, in which measured $\delta^{18}\text{O}_{\text{seawater}}$ and modern temperatures from the CTD data were inserted. Secondly, the determined Mg/Ca-temperatures were associated to in-situ temperatures measured by the CTD at the same station. The water depth in which $\delta^{18}\text{O}_{\text{calcite}}$ matches $\delta^{18}\text{O}_{\text{equilibrium}}$ and Mg/Ca temperatures fit in-situ temperatures is taken as the ACD of a species. A more detailed description about the ACD determination at the Manihiki Plateau is given in Chapter 3.2.5.

In the EEP, the deep ACD in sub-thermocline waters of *G. hexagonus* was validated by using measured $\delta^{18}\text{O}_{\text{calcite}}$ of the near core-top sample (10 cm) of ODP Site 1240. These $\delta^{18}\text{O}_{\text{calcite}}$ values were compared to calculated $\delta^{18}\text{O}_{\text{equilibrium}}$ values at different water depths and hence, different temperatures. To calculate $\delta^{18}\text{O}_{\text{equilibrium}}$, several established $\delta^{18}\text{O}$ -paleotemperature equations [Epstein *et al.*, 1953; Shackleton, 1974; Kim and O’Neil, 1997; Bemis *et al.*, 1998] together with salinity and temperature data from the World Ocean Atlas (WOA09) [Antonov *et al.*, 2010; Locarnini *et al.*, 2010] were applied. A more detailed description about the ACD determination in the EEP is given in Chapter 4.2.2.

2.4 Stratigraphy of ODP Site 1240

Any paleoceanographic reconstruction is dependent on a sound age model. Pena *et al.* [2008] established the first age model for ODP Site 1240 by a combination of radiocarbon dating and Antarctic ice core stratigraphy. Seventeen monospecific samples of planktonic foraminifer *N. dutertrei* were analysed for radiocarbon, which were calibrated with the marine dataset MA-

RINE 04 in parts younger than 20 kyr and the *Fairbanks et al.* [2005] marine calibration dataset for older sections. For detailed information about the radiocarbon calibration, the reader is referred to *Pena et al.* [2008]. To reconstruct past ocean circulation and nutrient cycling older than MIS 3, the newly generated benthic isotope record (*Cibicides* spp., sampled and measured by Patricia Povea, University of Barcelona) was used to refine the existing age model. In this revision, the benthic $\delta^{18}\text{O}_{\text{Cibicides}}$ record was aligned graphically to the global benthic $\delta^{18}\text{O}$ reference stack LR04 [*Lisiecki and Raymo*, 2005] using the software AnalySeries 2.0 [*Paillard et al.*, 1996]. Beyond the benthic isotope record of ODP Site 1240, the newly generated $\delta^{18}\text{O}$ record of deep-dwelling planktonic foraminifera *G. hexagonus* and the existing record of surface-dwelling planktonic species *G. ruber* [*Pena et al.*, 2008] were also graphically tuned to the LR04 stack. In addition, the ash layer “L” with a previously estimated age of 230 ± 10 kyr [*Ninkovich and Shackleton*, 1975] was considered as well.

In *Chapter 5*, the long-term *G. hexagonus* record of ODP Site 1240 was compared to a published data set from a Bering Sea sediment core (U1342; 54.83°N , 176.92°E , 818 m) [*Knudson and Ravelo*, 2015a] and a published sediment record from the South Pacific (SO136-003/MD06-2990; 42.19°S , 169.55°E , 943 m) [*Ronge et al.*, 2015]. The age models of both cores were again refined using radiocarbon dates (where available) and visual alignment to the global benthic stack LR04. A more detailed description about the revised stratigraphy and the newly generated age points for all three sediment cores is given in *Chapter 5.2.2* and *Table S5.7.1*.

Abstract

Insight into past changes of upper ocean stratification, circulation, and nutrient signatures rely on our knowledge of the Apparent Calcification Depth (ACD) and ecology of planktonic foraminifera, which serve as archives for paleoceanographic relevant geochemical signals. The ACD of different species varies strongly between ocean basins, but also regionally. We constrained foraminiferal ACDs in the Western Pacific Warm Pool (Manihiki Plateau) by comparing stable oxygen and carbon isotopes ($\delta^{18}\text{O}_{\text{calcite}}$, $\delta^{13}\text{C}_{\text{calcite}}$) as well as Mg/Ca ratios from living planktonic foraminifera to *in-situ* physical and chemical water mass properties (temperature, salinity, $\delta^{18}\text{O}_{\text{seawater}}$, $\delta^{13}\text{C}_{\text{DIC}}$). Our analyses point to *Globigerinoides ruber* as the shallowest dweller, followed by *Globigerinoides sacculifer*, *Neogloboquadrina dutertrei*, *Pulleniatina obliquiloculata* and *Globorotaloides hexagonus* inhabiting increasingly greater depths. These findings are consistent with other ocean basins; however, absolute ACDs differ from other studies. The

uppermost mixed-layer species *G. ruber* and *G. sacculifer* denote mean calcification depths of ~95 m and ~120 m, respectively. These western Pacific ACDs are much deeper than in most other studies and most likely relate to the thick surface mixed layer and the deep chlorophyll maximum in this region. Our results indicate that *N. dutertrei* appears to be influenced by mixing waters from the Pacific Equatorial Divergence, while *P. obliquiloculata* with an ACD of ~160 m is more suitable for thermocline reconstructions. ACDs of *G. hexagonus* reveal a deep calcification depth of ~450 m in oxygen-depleted, but nutrient-rich water masses, consistent to other studies. As the $\delta^{13}\text{C}$ of *G. hexagonus* is in near-equilibrium with ambient seawater, we suggest this species is suitable for tracing nutrient conditions in equatorial water masses originating in extra-tropical regions.

3.1 Introduction

Geochemical signals of planktonic foraminifera shells (= tests) are frequently used for paleoceanographic studies as they well reflect past environmental conditions [e.g. *Shackleton, 1974; Ravelo and Fairbanks, 1992; Nürnberg, 1995; Nürnberg et al., 1996; Bemis et al., 1998; Elderfield and Ganssen, 2000; Lea et al., 2000*]. Many species, however, are known to migrate through the water column during their life cycle and thus, their implemented geochemical signals most likely provide an integrated signal across both the entire water depth range and the entire ontogenetic (calcification) cycle of the species [e.g. *Hemleben and Bijma, 1994*]. Hence, the foraminiferal habitat depths determined by these geochemical signals are best described by the term Apparent Calcification Depth (ACD). It should be noted that the shell weight and therefore the chemical signature of the shell as a whole is mainly determined by the chemical composition of the last few chambers.

Approaches using planktonic foraminifers as biotic carriers of geochemical signals generally emphasize the importance of the knowledge of foraminiferal ACDs. Since the first plankton tow studies of *Bé [1959, 1962]*, efforts were launched to most reliably define the foraminiferal depth habitat [*Thunell and Honjo, 1981; Fairbanks et al., 1982; Thunell et al., 1983*]. With the development of geochemical analysis on foraminiferal tests, it was further possible to assess foraminiferal ACD [*Emiliani, 1955; Shackleton, 1974; Nürnberg, 1995; Faul et al., 2000; King and Howard, 2005; Regenberget al., 2009; Steph et al., 2009; Wilke et al., 2009; Birch et al., 2013; Wejnert et al., 2013*]. These studies reveal significant regional intraspecific differences in the ACD [*Faul et al., 2000; Steph et al., 2009*]. The species *Globigerinoides ruber*, for example, is often referred to as a “surface dweller”, i.e. living within the upper 30 m of the water column [*Hemleben et al., 1989; Faul et al., 2000; Steph et al., 2009; Birch et al., 2013*]. However, in cases of high sea-surface temperatures (SST) and a deep chlorophyll maximum (DCM), it has been shown to descend and calcify in deeper waters [*Fairbanks et al., 1982; Wejnert et al., 2013*]. Contrary, the ACDs of *Neogloboquadrina dutertrei* scatter within 40 – 200 m water depth range [*Hemleben et al., 1989; Dekens et al., 2002; Steph et al., 2009; Faul et al., 2000; Nürnberg et al., 2015*].

Particularly, during strong upwelling the ACD depth can shoal from within the thermocline to distinctly shallower waters [Loubere, 2001]. As the studies are scattered over the world oceans, reliable estimations of the ACDs of planktonic foraminifera in a specific area remains a challenge, which is further hampered by logistical difficulties.

The Western Pacific Warm Pool (WPWP) is the largest warm water area on Earth with SSTs consistently higher than 28°C (Figure 3.1a) [Yan *et al.*, 1992]. The WPWP deep thermocline (~175 – 300 m in the centre of the WPWP) [Andreason and Ravelo, 1997] allows for a large heat capacity, making it the major source of heat and moisture transfer from low to high latitudes. In contrast, in the eastern equatorial Pacific (EEP) the thermocline reaches depths as shallow as

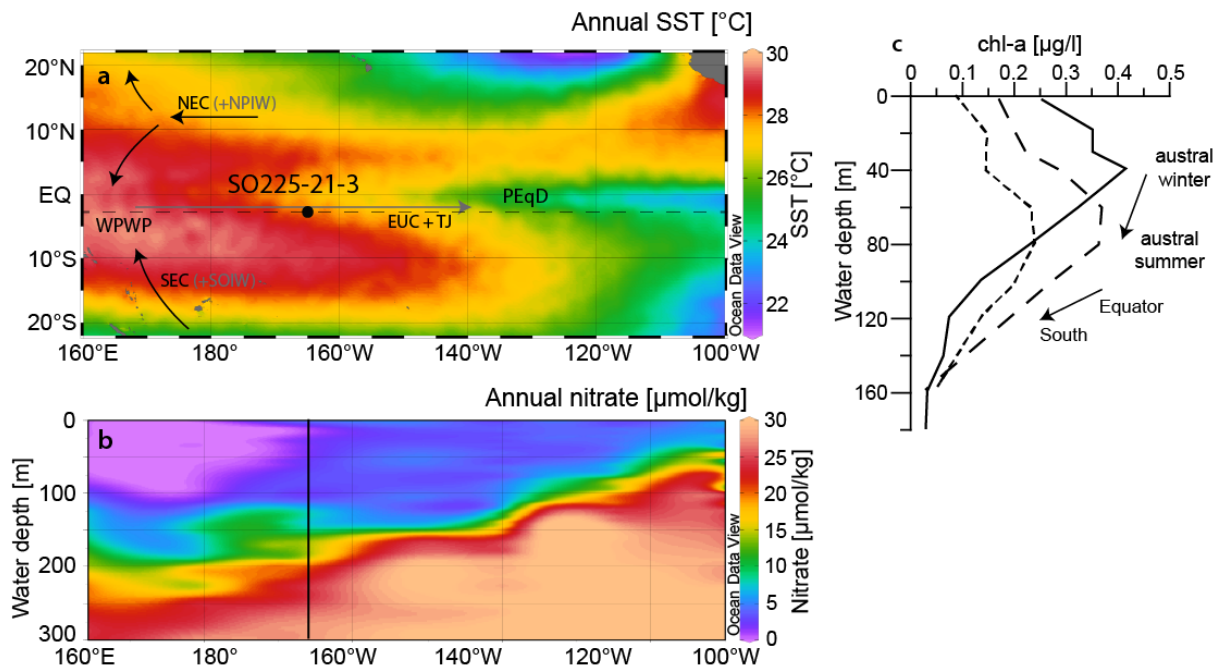

Figure 3.1. Upper ocean conditions of the equatorial Pacific. a: Annual sea-surface temperatures (SSTs) with multinet position SO225-21-3 and selected profile line shown in *b* (dashed line). WPWP denotes the Western Pacific Warm Pool, PEqD the Pacific Equatorial Divergence. Major surface (black) and intermediate (grey) currents are indicated with arrows; NEC = North Equatorial Current fed by the NPIW = North Pacific Intermediate Water, SEC = South Equatorial Current fed by the SOIW = Southern Ocean Intermediate Water, and EUC + TJ = Equatorial Undercurrent and Tsuchiya Jets [after Tomczak and Godfrey, 1994; Firing *et al.*, 1998; Rowe *et al.*, 2000]. b: Longitudinal depth section of annual nitrate along 3°S (see dashed line in *a*) with multinet position SO225-21-3 (black vertical line). Temperature map and section were generated with Ocean Data View [Schlitzer, 2012] using World Ocean Atlas 13 Data [a; Locarnini *et al.*, 2013] and GLODAP bottle data [b; Key *et al.*, 2004]. c: Chlorophyll-a concentration of the upper 200 m showing a seasonal and latitudinal change in the depth of the deep chlorophyll maximum. Profiles taken from FLUPAC cruise (black line, 0°, 164°W, October 1994) [Blain *et al.*, 1997], *Alizé 2* cruise at 0°, 165°W (wide striped line, February 1991) [Reverdin *et al.*, 1991] and *Alizé 2* cruise at 2.5°S, 168°W (narrow striped line, February 1991) [Reverdin *et al.*, 1991], respectively.

30 m [Locarnini *et al.*, 2013]. This asymmetric behaviour is also clearly seen in the zonal nitrate section (Figure 3.1b), which points towards overall oligotrophic conditions in the WPWP and contrasting with fertile conditions in the EEP. Fluctuations in size and temperature of the WPWP are important drivers for the El Niño Southern Oscillation (ENSO), the Asian monsoon system and, through atmospheric teleconnections, the global climate system [Sagawa *et al.*, 2012]. Despite the importance of the WPWP in the climate system, only little information about foraminiferal ACDs are available. To-date, the limited number of studies from the WPWP have concentrated on reconstructing upper ocean conditions with known ACDs from different regions [e.g. Wara *et al.*, 2005; Russon *et al.*, 2010] or focused on foraminiferal assemblages from the center of the WPWP near New Guinea [Kawahata *et al.*, 2002; Yamasaki *et al.*, 2008], or on plankton tows and surface sediments from the central equatorial Pacific [Watkins *et al.*, 1996; Lynch-Stieglitz *et al.*, 2015].

Our multinet study from the Manihiki Plateau attempts for the first time to define the modern ACDs of selected planktonic foraminifera at the south-eastern margin of the WPWP. Five modern planktonic foraminiferal species are studied: *G. ruber* (white), *Globigerinoides sacculifer*, *N. dutertrei*, *Pulleniatina obliquiloculata* and *Globorotaloides hexagonus*. We measured stable oxygen and carbon isotopes ($\delta^{18}\text{O}_{\text{calcite}}$, $\delta^{13}\text{C}_{\text{calcite}}$) as well as Mg/Ca ratios on the foraminiferal calcite and compared these data to *in-situ* physical and chemical seawater characteristics (temperature, salinity, $\delta^{18}\text{O}_{\text{seawater}}$, dissolved inorganic carbon $\delta^{13}\text{C}_{\text{DIC}}$). By doing so, we were able to better constrain species-specific ACD in an area with the thickest and warmest mixed layer on Earth and to determine the species-specific carbon-isotope disequilibrium. By doing so, we developed a great understanding of regional foraminiferal ACDs in the WPWP. We were then able to define to what extent the geochemical measurements deviate from predictions based on empirical relationships. Our study can be used to inform on what species to use for upper ocean water mass reconstructions of WPWP internal dynamics.

3.1.1 Foraminiferal ecological preferences and hydrographic setting

The abundance of planktonic foraminiferal species is strongly affected by environmental parameters such as, the thermal structure of the water column, salinity, and food supply [e.g. Bijma *et al.*, 1990; Watkins *et al.*, 1996; King and Howard, 2003; Žarić *et al.*, 2005]. Culture experiments and surface-sediment samples indicate temperature as one of the major environmental parameters affecting the foraminiferal biogeographic distribution [Bé and Tolderlund, 1971; Bijma *et al.*, 1990; Morey *et al.*, 2005]. Even though most planktonic foraminifera have a large temperature tolerance of about 14 – 32°C [Bijma *et al.*, 1990; Mulitza *et al.*, 1998], they all have an individual, far more restricted optimum temperature (e.g. 23.5°C for *G. sacculifer*) at which chamber formation, gametogenesis, and food acceptance is highest [Bijma *et al.*, 1990]. In contrast, the salinity tolerance range in planktonic species is wider than variations encountered in the open oceans (e.g. 24 – 47 in *G. sacculifer*) [Bijma *et al.*, 1990],

thus, salinity plays most likely a marginal role for the foraminiferal distribution. Salinity, however, can influence the vertical distribution of planktonic foraminifera indirectly by changing the density structure of the water column and thereby restricting vertical movement and the accumulation of nutrients in certain depths [Bijma *et al.*, 1990].

The WPWP at the Manihiki Plateau is characterized by high annual SSTs and sea-surface salinities (SSS) of $28 \pm 0.2^\circ\text{C}$ and 35 ± 0.03 (psu), respectively [Locarnini *et al.*, 2013; Zweng *et al.*, 2013]. Sediment trap results from the WPWP reveal that despite the small seasonal SST range of $\pm 0.2^\circ\text{C}$, planktonic foraminifera are not present all year round in high abundances [Kawahata *et al.*, 2002; Lin *et al.*, 2004]. The production is rather controlled by local nutrient availability and light intensity [Kawahata *et al.*, 2002]. As a consequence of the oligotrophic surface waters in the WPWP, with nutrient concentrations of <0.1 mM NO_3^- and <0.2 mM PO_4 [Blanchot *et al.*, 2001; Le Borgne *et al.*, 2002; Rafter and Sigman, 2015], primary production is low and foraminiferal fluxes are modest (mean 171 shells $\text{m}^{-2} \text{day}^{-1}$) [Kawahata *et al.*, 2002]. In contrast, the high-nutrient low-chlorophyll (HNLC) region of the Pacific Equatorial Divergence is enriched in macronutrients (>3 mM NO_3^- ; >0.4 mM PO_4) and foraminiferal fluxes are higher (up to 430 shells $\text{m}^{-2} \text{day}^{-1}$) [Thunell and Honjo, 1981]. Through a complex and highly dynamic current system [e.g. Wyrki and Kilonski, 1984; Fine *et al.*, 1994; Tomczak and Godfrey, 1994; Johnson and Moore, 1997; Rowe *et al.*, 2000; Goodman *et al.*, 2005; Grenier *et al.*, 2011], including the South Equatorial Current (SEC), the persistent eastward-directed sub-surface Equatorial Undercurrent (EUC) and the Tsuchiya Jets [after Tsuchiya, 1972], nutrients are transported via intermediate and mode waters from the extra-tropical HNLC regions to the thermocline of the western equatorial Pacific and upwell along the equator in the Pacific Equatorial Divergence.

In the vicinity of the nutricline, chlorophyll-a concentrations reach a maximum between 40 and 90 m water depths in the WPWP indicating the DCM (Figure 3.1c). Planktonic foraminifera respond to the distribution of chlorophyll and high abundances are often associated with the DCM [Fairbanks *et al.*, 1982; Schiebel *et al.*, 2001]. Even though the depth of the DCM does not change significantly from east to west [Le Borgne *et al.*, 2002], it changes meridionally. Upwelling decreases away from the equator and, as a consequence, the DCM deepens. The DCM depth also varies seasonally: while the DCM at the equator is situated at ~ 60 m (range $\sim 40 - 80$ m, values >0.3 mg m^{-3}) during austral summer, it shoals during autumn and reaches its shallowest position during austral winter ($25 - 70$ m, maximum 40 m) [Le Borgne *et al.*, 2002].

Variations in upper ocean temperatures, depth of the thermocline and hence, nutrients in the upper water column, are influenced by the ENSO climate phenomenon [Collins *et al.*, 2010]. Nevertheless, the Oceanic Niño Index (ONI), a standard for identifying El Niño and La Niña events through averaging SST anomalies, was only slightly increased ($0.2 - 0.4^\circ\text{C}$) from August to December 2012 [NOAA, 2015a], thus indicating only a tendency for a very weak El Niño (ONI $>0.5^\circ\text{C}$).

3.2 Material and Methods

3.2.1 Sample material

During the RV SONNE cruise SO225, *in-situ* temperature, salinity and oxygen measurements were conducted with a Conductivity-Temperature-Depth (CTD) device equipped with a 24 in each case 10 L bottle-rosette system (SO225-21-1; 3.05°S, -165.056°W) [Werner *et al.*, 2013]. The water column was sampled at 15 depths, and for each water depth a 50 ml and a 100 ml subsamples was taken and stored in glass bottles for $\delta^{13}\text{C}$ and $\delta^{18}\text{O}_{\text{seawater}}$ measurements, respectively. Water samples for carbon isotope analysis were poisoned with 100 μl of saturated HgCl_2 solution to prevent biological activity and sealed with beeswax to prevent interaction with air.

At the same location where SO225-21-1 was recovered, a multiple open/closing plankton net was run during the night at the northernmost edge of the Manihiki Plateau in the WPWP (SO225-21-3) [Werner *et al.*, 2013] (Figure 3.1a). The multinet (HydroBios, Kiel) with a square mouth opening of 50 x 50 cm, 55 μm mesh size, and five net bags allowed stratified vertical sampling in five depth intervals within the first 500 m of the water column. The depths were selected after viewing the CTD cast and thus, included the sea surface (0 – 50 m), sub-surface (50 – 100 m), upper thermocline (100 – 200 m), lower thermocline (200 – 300 m) and sub-thermocline (300 – 500 m). These depth intervals are often investigated in paleoceanographic research [e.g. Spero *et al.*, 2003; Wara *et al.*, 2005; Kiefer *et al.*, 2006; Pena *et al.*, 2008; Regenberg *et al.*, 2009; Nürnberg *et al.*, 2015], highlighting the need to better understand the ACD of the species calcifying in these depths. Since the area is known for low primary production, we selected relatively large net depth intervals to capture enough material for our analyses. Immediately after collection, plankton tow samples were preserved with an Ethanol-Bengal Rose solution.

3.2.2 Handling foraminiferal assemblage counts

In the laboratory, plankton net samples were sieved over 1000 μm and 63 μm . Material >1000 μm was analysed for spinose species attached to particulate organic matter. Within the fraction 63 – 1000 μm intact planktonic foraminifera >125 μm were wet picked using a binocular microscope and dried afterward. As all individuals contained coloured cytoplasm in the early chambers, we infer that the samples were collected alive or shortly after they died. Smaller-sized planktonic foraminifera are more difficult to define taxonomically. As we primarily focus on size fractions well established for paleoceanographic purposes (>250 μm), only foraminifera >125 μm were counted. Depending on the amount of material, samples were either quantitatively split into aliquots and approximately 200 – 400 foraminifera were identified or the whole sample was counted (Supplement Table S3.5.1). Further, we calculated the density of different species over the netted depth range using the formula: $\# / (a \cdot a) \cdot b$; with $\#$ being the number of counted

specimen, a being the multinet-opening in meters and b the depth interval the respective net was hauled.

Planktonic foraminiferal taxonomy follows the work of *Parker* [1962], *Bé* [1977] and *Hemleben et al.* [1989]. We are aware that *G. ruber* (white) exists in different morphotypes. The determination of the morphotypes *sensu strictu* (s.s.) and *sensu lato* (s.l.) follows the concept of *Wang* [2000], in which *G. ruber* s.s. has spherical chambers sitting symmetrically over previous sutures with high arched apertures and *G. ruber* s.l. corresponds to more compressed subspherical chambers with a small aperture. These different morphotypes have been shown to dwell at slightly different water depths, yet always at the sea surface [e.g. *Wang*, 2000; *Steinke et al.*, 2005; *Kuroyanagi et al.*, 2008]. For our analyses we selected mainly the morphotype s.s., but due to limited amount of material, we also included some specimen of the slightly deeper-dwelling morphotype s.l. for the isotope analyses when necessary.

3.2.3 Determination of Mg/Ca ratios and calculation of water temperatures

Mg/Ca ratios of planktonic foraminiferal calcite were measured to assess the water temperature during test growth. Prior to the analysis, the cytoplasm within the test was removed by treating the foraminiferal shells with 7 % sodium hypochlorite (NaClO) before rinsing with deionised water. Intact specimens were selected from the 320 – 760 μm size fraction as a narrower size range was prevented by the rather low amount of material (Table 3.1).

The geochemical analyses were obtained with the Excimer ArF 193 nm laser ablation system from NEW Wave ESI with a two-volume ablation cell design, coupled to an Agilent 7500cs Inductively Coupled Plasma-Mass Spectrometer (LA-ICP-MS) at GEOMAR. This micro-analytical technique enables the measurement of element/Ca through the shell wall of individual chambers. However, for the habitat assessment we use the mean Mg/Ca ratios of all the chambers in the final whorl of each shell that could be targeted with the laser. *Hemleben and Bijma* [1994] demonstrated that the vast majority of the shell mass and therefore most of the geochemical signal is contained in the last few chambers. Measuring as many chambers as possible is important as Mg/Ca seems to vary randomly from chamber to chamber in cultures under constant environmental conditions [*de Nooijer et al.*, 2014]. Thus, we analysed as many chambers as possible to ensure that we have sampled as much of the shell as possible. Culturing studies have investigated the difference between whole-test calibrations and Mg/Ca-temperature equations based on Mg/Ca measurements of the last chambers and found no significant difference between them [*Kunioka et al.*, 2006; *Dueñas-Bohórquez et al.*, 2009, 2011; *Spero et al.*, 2015]. The laser was targeted on the test surface, ablating through the test wall with a 50 μm diameter spot size, and stopped when the wall was penetrated. Ablations were conducted in a He atmosphere and the laser energy density was between 0.97 and 1.85 J/cm^2 with a laser repetition rate of 5 Hz. The ablation was done on as many chambers as possible (f to f-4), always proceeding from the

Table 3.1. Overview of net collections of five paleoceanographically important foraminiferal species. The depth ranges from which the foraminifera were selected, species abundances, foraminiferal shell sizes, number of tests measured as well as geochemical analyses are given.

| Species | Net depth [m] | #/m ³ | Shell size [range in μm] | Number of tests measured | Accomplished measurement | | |

outside of the test towards the inside. Time-resolved signals of ²⁴Mg were selected for integration and the mean background intensities (gas blank) were subtracted. Signal intensities were internally standardised to ⁴³Ca to account for variations in ablation yield. Mg/Ca intensity ratios were calibrated with analyses of the international reference NIST 610 and NIST 612 glasses after

every 10 sample spots [using values from *Jochum et al.*, 2011], which were ablated with a higher energy density (around 2.65 J/cm²). A powder pellet of the powdered reference material JCP-1 (*Porites* sp.) was ablated like a sample and the repeated measurements during the analytical session (n = 6) gave a relative standard deviation of 7.4 % (1 σ) for Mg/Ca with an average value of ~3.707 mmol/mol that is 11 % less than the solution ICP-MS consensus value from *Hathorne et al.* [2013] (4.199 mmol/mol).

Core top and culture studies point towards a species-specific dependency of the Mg incorporation into foraminiferal tests due to the interplay of biological processes and ecological behaviour [e.g. *Nürnberg et al.*, 1996; *Lea et al.*, 1999; *Regenberg et al.*, 2009; *Nehrke et al.*, 2013; *Mewes et al.*, 2015]. As a consequence, various species-specific calibrations have been established that have all basic similarities, but produce significantly different temperature estimates when applied to the same Mg/Ca ratios. Hence, the accurate selection of the applied calibration curve is crucial. To find the most reliable calibration curve for each investigated foraminiferal species from the multinet samples, we converted the measured whole-shell foraminiferal Mg/Ca ratios (Supplement Table S3.5.2) into temperatures using generic and species-specific equations if available (Supplement S3.5.3, Supplement Table S3.5.3). At the depth interval in which a species was found in highest abundance on the Manihiki Plateau (see *Chapter 3.3.2*), we determined the mean temperature during sampling time from both CTD data and the seasonal range in temperature from the WOA13 data [*Locarnini et al.*, 2013] at the same location. By comparing the *in-situ* temperatures with the Mg/Ca-derived temperatures, we identified the most suitable calibration equation for each species at our study site (Table 3.2, Supplement S3.5.3).

Table 3.2. Equations used to convert foraminiferal Mg/Ca into temperatures and to calculate equilibrium $\delta^{18}\text{O}_{\text{equilibrium}}$.

| Species | Type of sample | Water mass | Equation | | | Reference |
|---|-----------------------------|--|-----------------------------|----------------------|------|--------------------------------------|
| $\text{Mg/Ca} = \text{B} \cdot \exp(\text{A} \cdot \text{T})$ | | | | | | |
| | | | $\frac{\text{B}}{\text{A}}$ | $\frac{1}{\text{A}}$ | | |

3.2.4 Stable isotope analyses

Stable oxygen and carbon isotope ratios ($\delta^{18}\text{O}_{\text{calcite}}$ and $\delta^{13}\text{C}_{\text{calcite}}$) of the foraminiferal tests (Table 3.1) were determined to estimate the ACD by comparing measured $\delta^{18}\text{O}_{\text{calcite}}$ to predicted $\delta^{18}\text{O}_{\text{calcite}}$ as well as to assess the deviation from prediction based on empirical relationships. The isotope ratios were measured on a ThermoScientific MAT 253 mass spectrometer coupled to an automatic carbonate preparation device Kiel CARBO IV at AWI. The isotope measurements were calibrated via the international standard NBS 19 to the VPDB scale. All results are given in the common δ -notation *versus* VPDB. The precision of the measurements, determined over a one-year period and based on repeated analysis of an internal laboratory standard (Solnhofen limestone), is ± 0.06 ‰ and ± 0.08 ‰ (1 σ) for carbon and oxygen isotopes, respectively.

Measurements of the oxygen isotope composition of seawater ($\delta^{18}\text{O}_{\text{seawater}}$) were performed on a ThermoScientific Delta S mass spectrometer and those for the seawater dissolved inorganic carbon isotope composition ($\delta^{13}\text{C}_{\text{DIC}}$) were made with a ThermoScientific MAT 252 coupled to a Gas Bench II at AWI. The $\delta^{18}\text{O}_{\text{seawater}}$ values are given in δ -notation *versus* VSMOW and $\delta^{13}\text{C}_{\text{DIC}}$ values *versus* VPDB. The precision determined over a one-year period is ± 0.03 ‰ (1 σ) for $\delta^{18}\text{O}_{\text{seawater}}$ and ± 0.1 ‰ (1 σ) for $\delta^{13}\text{C}_{\text{DIC}}$.

3.2.5 Estimation of the apparent calcification depth

We constrained the ACDs of selected planktonic foraminiferal species by combining two approaches. This enables us to assess the ACD with improved accuracy. First, we compared the measured foraminiferal $\delta^{18}\text{O}_{\text{calcite}}$ to calculated $\delta^{18}\text{O}_{\text{equilibrium}}$ values at different water depths and hence, different temperatures. The water depth from which $\delta^{18}\text{O}_{\text{calcite}}$ matches $\delta^{18}\text{O}_{\text{equilibrium}}$ is taken as the isotope ACD (Table 3.3). The expected $\delta^{18}\text{O}_{\text{equilibrium}}$ values were calculated using paleotemperature-equations of *Shackleton* [1974], *Kim and O'Neil* [1997], *Bemis et al.* [1998; *Orbulina universa* high light], and *Mulitza et al.* [2004] (Supplement Table S3.5.4). In them, we inserted our measured variables foraminiferal $\delta^{18}\text{O}_{\text{calcite}}$, seawater $\delta^{18}\text{O}$ (converted into VPDB by subtracting -0.27 ‰) [*Hut*, 1987], and modern temperatures from CTD data. Different equations were tested to show that relative species order in the water column is independent of the $\delta^{18}\text{O}$ -paleotemperature equation. The absolute isotope-ACDs, however, differ with each equation (Supplement Table S3.5.4). In cases where $\delta^{18}\text{O}_{\text{calcite}}$ values were lower than predicted $\delta^{18}\text{O}_{\text{equilibrium}}$ values at the sea surface, ACDs of 5 m water depth were assigned (Supplement Table S3.5.4). ACDs derived by *Shackleton* [1974] and *Kim and O'Neil* [1997] are similar at the sea surface. In deeper waters, *Shackleton's* [1974] equation produces markedly shallower isotope-ACDs than *Kim and O'Neils'* [1997]. On the other hand, the equations of *Bemis et al.* [1998] and *Mulitza et al.* [2004], that were both generated using planktonic foraminifera, yield deeper isotope-ACDs at all depths. Nevertheless, using *Mulitza et al.* [2004] for upper-ocean dwelling species (0 – 220 m), the number of samples with measured $\delta^{18}\text{O}_{\text{calcite}}$ that are lower than

Table 3.3. Specification of Apparent Calcification Depth (ACD) of foraminiferal species at Manihiki Plateau using (1) measured $\delta^{18}\text{O}_{\text{calcite}}$ values that were placed at water depths corresponding to theoretical $\delta^{18}\text{O}_{\text{equilibrium}}$ values depending on water temperature and salinity. (2) Mg/Ca derived temperature estimates placed at water depths corresponding to *in-situ* measured austral summer temperatures [Werner *et al.*, 2013] and seasonal World Ocean Atlas 2013 temperature ranges [Locarnini *et al.*, 2013]. Each line represents one single analysed sample.

the respective $\delta^{18}\text{O}_{\text{equilibrium}}$ at the sea surface is minimised. In deeper waters, however, the equation of *Mulitza et al.* [2004] yield isotope-ACDs of up to 660 m (Supplement Table S3.5.4), and these are deeper than the nets were hauled. As a consequence, we selected the equation by *Kim and O'Neil* [1997], which was calibrated using inorganic calcite, for sub-thermocline waters (220 – 500 m, Table 3.2). Seasonal variations in $\delta^{18}\text{O}_{\text{equilibrium}}$ due to varying temperature are considered by using temperature data from the WOA13 database to account for temperature variations during the foraminiferal life cycle (Table 3.3) [*Locarnini et al.*, 2013]. To assess the influence of species-specific offsets from $\delta^{18}\text{O}_{\text{equilibrium}}$, we corrected the measured $\delta^{18}\text{O}_{\text{calcite}}$ values for disequilibrium effects [values are taken from *Niebler et al.*, 1999 and *Steph et al.*, 2009] and recalculated the $\delta^{18}\text{O}$ -derived ACDs with the *Mulitza et al.* [2004] and *Kim and O'Neil* [1997] equations (Supplement Table S3.5.4).

In a second step, we compared the temperatures converted from the average Mg/Ca of living specimens (Table 3.1) to the ocean temperatures prevailing during the time of sampling (December 2012) at the sample location and placed the temperature-ACD at the according water depth (Table 3.3). To account for seasonal variations in the temperature record, we also compared the derived Mg/Ca temperatures to austral winter and austral summer temperatures (data from WOA13) (Table 3.3) [*Locarnini et al.*, 2013].

In a last step, we combined both ACD approaches and determined the mean ACD. We are aware, that we have an uneven distribution between $\delta^{18}\text{O}$ and Mg/Ca measurements (Table 3.1). Thereby, more credit is given towards the $\delta^{18}\text{O}$ -derived ACD. To validate the combined mean ACD, we used the mean temperature and mean $\delta^{18}\text{O}_{\text{calcite}}$ of the respective species and calculated the $\delta^{18}\text{O}_{\text{water}}$. For this purpose we selected different paleotemperature equations (Supplement S3.5.5, Supplement Table S3.5.5) and rearranged the equations for the $\delta^{18}\text{O}_{\text{water}}$. The $\delta^{18}\text{O}_{\text{water}}$ was then compared to the measured $\delta^{18}\text{O}_{\text{seawater}}$ (Supplement S3.5.5). It demonstrates that the calculated $\delta^{18}\text{O}_{\text{water}}$ displays the measured $\delta^{18}\text{O}_{\text{seawater}}$ curve and hence, supports the use of a combined isotope and Mg/Ca approach.

3.3 Results and Discussion

3.3.1 Hydrological conditions in the upper ocean water column

At the time of multinet sampling (December 2012) at station SO225-21 the mixed layer was characterized by a SST of 27.9°C, a SSS of 35.5, an oxygen concentration > 170 $\mu\text{mol/l}$ and a $\delta^{18}\text{O}_{\text{seawater}}$ of +0.5 ‰ (Figure 3.2). The SST and SSS agree well with the long-term WOA13 dataset [Locarnini *et al.*, 2013] showing a deep surface mixed layer (SML) extending to 105 m water depth, below which temperature decreases steadily. The main thermocline is located between 130 m and 230 m water depth and reflects an overall temperature decline of $\sim 16^\circ\text{C}$ (from 28°C to $\sim 12^\circ\text{C}$).

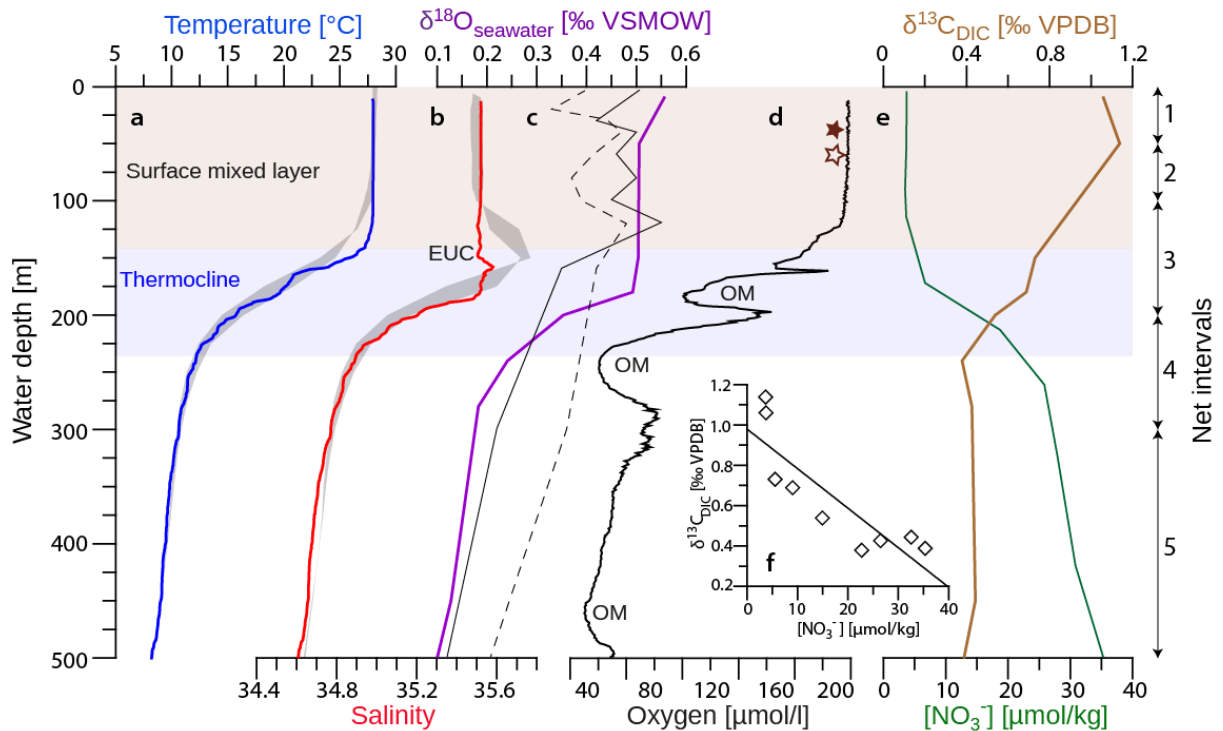

Figure 3.2. Water column characteristics of the uppermost 500 m at multinet station SO225-21-03 along the towed net intervals. a: Temperature and b: salinity profile from CTD casts in December 2012 (SO225-21-01) [Werner *et al.*, 2013]. Blue/red curves show the temperature/salinity during the time of multinet sampling with the position of the Equatorial Undercurrent (EUC). Grey shaded areas delineate long-term seasonal temperature and salinity variations [Locarnini *et al.*, 2013; Zweng *et al.*, 2013]. c: Measured $\delta^{18}\text{O}_{\text{seawater}}$ from CTD station SO225-21-01 (purple, this study); solid/dashed black lines indicate $\delta^{18}\text{O}_{\text{seawater}}$ at 160°W/168°W, respectively, using the Schmidt *et al.* [1999] database. d: Oxygen concentration from CTD cast in December 2012 [Werner *et al.*, 2013] showing three oxygen minima (OM). Dark brown stars indicate the chlorophyll-a maxima during austral winter (filled symbol) [Blain *et al.*, 1997] and austral summer (open symbol) [Reverdin *et al.*, 1991] (data shown in Figure 3.1c), e: $\delta^{13}\text{C}_{\text{DIC}}$ values measured on water samples from CTD casts (brown, this study) and nitrate concentration of the water column (green) obtained from GLODAP bottle data [Key *et al.*, 2004]. f:

Covariance between $\delta^{13}\text{C}_{\text{DIC}}$ and $[\text{NO}_3^-]$ at 3°S and 168°W yields a relationship of $\delta^{13}\text{C}_{\text{DIC}} = -0.02 * [\text{NO}_3^-] + 0.98$ ($r^2 = 0.73$). Arrows and numbers on the right denote the five net intervals of the multinet collection with sea surface (1), sub-surface (2), upper thermocline (3), lower thermocline (4) and sub-thermocline (5).

At the top of the thermocline, however, both temperature and salinity deviate from the long-term average (Figure 3.2a and b). The temperatures are up to 2°C warmer between 125 and 150 m. Salinities are significantly reduced between 125 and 160 m. These changes may indicate changes in the source area and speed of the EUC as a consequence of weaker trade winds in December 2012. In contrast, the comparison between $\delta^{18}\text{O}_{\text{seawater}}$ values from the sampling site to 1991-profiles at 160°W and 168°W [Schmidt *et al.*, 1999] reveals up to 0.2 ‰ heavier values (Figure 3.2c). As in the open ocean, $\delta^{18}\text{O}_{\text{seawater}}$ is mainly affected by the evaporation/precipitation balance [Dansgaard, 1964] with heavier values attributed to higher evaporation, we assume an increase in evaporation probably related to stronger trade winds from 1991 until December 2012. This agrees with model experiments that show an acceleration of Pacific trade winds due to the intensification of the Walker circulation over the period 1992 – 2011 [McGregor *et al.*, 2014]. Consequently, it seems that over the last decade trade wind strength and hence evaporation increased, but in December 2012 wind strength dropped for a short time, leading to a decrease in upwelling and thus to warmer and less saline waters at the top of the thermocline. Further support comes from the equatorial Pacific Zonal Wind field models in November – December 2012 [NOAA, 2015b] and from the slightly increased Oceanic Niño Index (ONI) that indicates a very weak El Niño (ONI >0.5°C) and consequently weaker prevailing winds (see also *Chapter 3.1.1*) [NOAA, 2015a].

Associated with the thermo- and halocline, oxygen concentrations decline in two steps, which points to two oxygen minima (OM) located at ~180 m and ~250 m (Figure 3.2d). Possibly both OM belong to one expansive OM that is separated by a chlorophyll maximum in which oxygen is produced. However, to verify this hypothesis a deeper chlorophyll-a profile extending to at least 300 m water depth is needed. Oxygen concentrations further decline below the thermocline towards a less pronounced OM in ~450 m with concentrations of 57 $\mu\text{mol/l}$. The strongest OM in December 2012 (concentration of 44 $\mu\text{mol/l}$) is located at ~660 m water depth below the hauled nets.

At the multinet sampling site, the overall range in $\delta^{13}\text{C}_{\text{DIC}}$ is from ~-0.4 ‰ to ~-1.1 ‰, achieving a maximum in the surface waters (Figure 3.2e). The $\delta^{13}\text{C}_{\text{DIC}}$ data start to decline below ~50 m and gradually decrease throughout the thermocline in response to remineralisation processes and the release of ^{12}C to the ambient seawater. The overall shape of the $\delta^{13}\text{C}_{\text{DIC}}$ profile is anticorrelated to the GLODAP $[\text{NO}_3^-]$ profile [Key *et al.*, 2004]. With increasing nitrate concentrations, the $\delta^{13}\text{C}_{\text{DIC}}$ values decrease simultaneously due to the concurrent uptake of ^{12}C and nutrients during photosynthesis. The slope of this relationship depends on the fractionation of

$\delta^{13}\text{C}$ during photosynthesis. Our $\delta^{13}\text{C}_{\text{DIC}}:\text{[NO}_3\text{]}$ comparison yield a relationship of: $\delta^{13}\text{C}_{\text{DIC}} = -0.02 * \text{[NO}_3\text{]} + 0.98$ ($r^2 = 0.73$) (Figure 3.2f).

3.3.2 Vertical distribution of planktonic foraminifers in the water column

A total number of 20 taxa have been identified in the net collection from the Manihiki Plateau of which 16 could be identified on the species level (Supplement Table S3.5.1). Most common and abundant species (>10 %) are: *Globorotalia menardii* (mean relative abundance (MRA) 22.7 %, range 7.8 % – 26.4 %), *Pulleniatina obliquiloculata* (MRA 15.4 %, range 5.2 – 19.6 %), *Globigerinita glutinata* (MRA 13.8 %, range 5.7 – 30.1 %), *Globigerinella* spp. (MRA 12.8 %, range 3.6 – 16 %) and *Globorotalia* spp. (MRA 10 %, range 3.6 – 10.8 %). Less abundant species (2 – 10 %) are *Globigerinoides sacculifer* (MRA 7.2 %, range 3.6 – 9.8 %), *Neogloboquadrina dutertrei* (MRA 5.1 %, range 2.6 – 6.3 %), *Globigerinoides ruber* (white) (MRA 2.9 %, range 0.8 – 5 %) and *Globoquadrina conglomerata* (MRA 2.1 %, range 1 – 2.8 %). All other taxa occur in very low abundances (MRA <2 %). For further analyses, we selected four species often used in paleoceanographic research (*G. ruber*, *G. sacculifer*, *N. dutertrei*, and *P. obliquiloculata*) [e.g. Spero et al., 2003; Kiefer et al., 2006; Pena et al., 2008; Leduc et al., 2009; Nürnberg et al., 2015; Rippert et al., 2015], although other species had a higher abundance in the water column during our expedition. The highest abundances (in #/m^3) of the selected species were found between 0 and 100 m water depth (Figure 3.3). This is the depth interval with highest chlorophyll-a vertical concentrations (Figure 3.1c), supporting the idea that nutrient distribution mainly determines the vertical distribution of foraminiferal species [Hemleben et al., 1989; Schiebel et

Figure 3.3. Planktonic foraminiferal abundances (in specimen/ m^3) for five paleoceanographically important species in this study plotted with (on the left) *in-situ* data of temperature [Werner et al., 2013] and chlorophyll-a (brown) [Reverdin et al., 1991]. Arrows and numbers on the right denote the five net intervals of the multinet collections with sea surface (1), sub-surface (2), upper thermocline (3), lower thermocline (4) and sub-thermocline (5).

al., 2001; *Schiebel and Hemleben*, 2005].

Sediment trap and surface sediment studies from tropical areas indicate that *G. sacculifer* and *G. ruber* dominate the foraminiferal abundances with >5 % and >10 %, respectively, with similar abundances in the Atlantic and Pacific for *G. sacculifer* (~10 %) and higher abundances of *G. ruber* in the Atlantic compared to the Pacific (~40 to ~18 %, respectively) [*Thunell and Honjo*, 1981; *Ravelo et al.*, 1990; *Kawahata et al.*, 2002; *Schmuker and Schiebel*, 2002; *Yamasaki et al.*, 2008]. Our MRAs, however, show abundances of these species of <10 % in December 2012. This is in agreement with sediment trap analyses from the West Caroline Basin (New Guinea) deployed over a one year interval that revealed a seasonal bias in foraminiferal shell flux with lowest fluxes for *G. ruber* and *G. sacculifer* in December [*Kawahata et al.*, 2002]. Further, our study site at the northernmost rim of the Manihiki Plateau is situated at the transition from the WPWP to the Pacific Equatorial Divergence [*Le Borgne et al.*, 2002]. High SSTs at the sampling site suggest the dominant influence from the WPWP. On the other hand, surface nitrate concentrations of $3.6 \pm 0.1 \mu\text{mol/kg}$ (168.7°W, -3°S, 168°W) [*Key et al.*, 2004] are higher than nitrate concentrations typically characteristic for the WPWP (<0.1 $\mu\text{mol kg}^{-1}$) [*Blanchot et al.*, 2001; *Rafter and Sigman*, 2015] and rather suggest a presumably slight increased influence of the Pacific Equatorial Divergence. Additionally, repeated station analyses on nitrate concentrations along the equator also reveal increasing nitrate concentrations at the base of the SML during austral summer [*Rafter and Sigman*, 2015]. Since the hydrographic data record a general decrease in upwelling (Figure 3.2), higher nutrient concentrations probably result from increased diapycnal mixing [*Rafter and Sigman*, 2015]. As a consequence of these higher nutrient concentrations primary production was increased, which can be seen in the higher chlorophyll-a concentrations determined from Ocean Colour Data during sampling [*NASA Ocean Biology*, 2015]. The resulting higher amounts of nutrients and food most likely explain the relatively high abundances of *G. menardii*, *P. obliquiloculata*, and *G. glutinata*, which are often associated within or are found at the border of fertile tropical areas [*Watkins et al.*, 1998]. A higher abundance of these species, in turn, will compete with *G. ruber* and *G. sacculifer*, and thereby, decrease their abundance as seen in our multinet analyses.

Despite the low MRA of 1.7 %, *G. hexagonus* dominates the foraminiferal assemblage with roughly 45 % at 300 – 500 m water depth (Supplement Table S3.5.1). Therefore, we included this species in our analyses as well. The high numbers below 300 m demonstrate its adaptation to deeper, colder waters. To date, there is only sparse information about the seasonal and the reproductive cycle of this species. Time series sediment traps from the Peru-Chile Current indicate that in contrast to most other deep-dwelling species, *G. hexagonus* is present year-round [*Marchant et al.*, 1998]. Taking the preference for an ecologically more uniform habitat with smaller seasonal variations (compared to the shallow ocean) into account, the reproductive cycle of *G. hexagonus* could be similar to other deep-dwelling species (possibly once per year) [*Schiebel and Hemleben*, 2005]. However, more studies on their depth and seasonal distribution as well as their ecology are required to infer a specific calcification depth.

3.3.3 Foraminiferal apparent calcification depth

By combining the isotope-based ACDs (Figure 3.4a) with the Mg/Ca-based ACDs (Figure 3.4b), we can reliably infer the overall range of species-specific ACDs (Figure 3.4c, Table 3.3). Relative ACDs within a foraminifera assemblage point to *G. ruber* as the shallowest dweller, followed with increasing depth by *G. sacculifer*, *N. dutertrei*, *P. obliquiloculata* and *G. hexagonus* being the deepest dwelling species. The ACDs of these species are similar to that shown for other ocean basins [e.g. *Ravelo and Fairbanks*, 1992; *Dekens et al.*, 2002; *Regenberg et al.*, 2009; *Steph et al.*, 2009; *Rincón-Martínez et al.*, 2011; *Birch et al.*, 2013; *Lynch-Stieglitz et al.*, 2015]. However, absolute values differ between and within ocean basins. Furthermore, a large discrepancy between the $\delta^{18}\text{O}$ -derived ACDs and the Mg/Ca temperature-derived ACDs can sometimes be observed. This is possibly the result of a combination of various effects:

1) Mg/Ca was measured on different and sometimes larger tests than tests used for isotope measurements due to logistical obstacles (Table 3.1). The test sizes used for the Mg/Ca ablation of this study are unusually large for Mg/Ca analyses that often concentrate on test sizes between 250 and 500 μm [e.g. *Dekens et al.*, 2002; *Anand et al.*, 2003]. However, as we were limited by the amount of foraminiferal tests within the net samples for the measurements, we had to enlarge the size fraction. Studies have shown that there might be a size-related control on the incorporation of Mg into the foraminiferal shell with decreasing Mg/Ca values with increasing size possibly due to the additional formation of gametogenic calcite [*Elderfield et al.*, 2002; *Ni et al.*, 2007; *Friedrich et al.*, 2012]. However, it was also shown that the amount of gametogenic calcite was constant (ca. 4 μg) independent of size [*Hamilton et al.*, 2008]. The fact that the foraminifera we analysed often still had their spines or remains thereof indicates that gametogenic calcite was not present. Nonetheless, isotope and Mg/Ca samples from a similar size range (Table 3.1) show comparable ACDs (Table 3.3) and thus, we consider the large size Mg/Ca-derived ACD estimations as reliable.

2) For laser ablation, only one single foraminiferal test was needed, but for isotope measurements more than one shell per species was used (Table 3.1). Thereby, the inter-sample variability was lower in isotope measurements, which could have led to less variability in ACD estimates.

3) The $\delta^{18}\text{O}$ -paleotemperature equations applied in this study provide an additional reason for varying ACDs between the measurements. This holds true especially for mixed layer species as they are exposed to greater variability of water characteristics and thus, tend to have more ecology-related chemical effects. Mg/Ca was converted into temperatures using species-specific calibration equations (Table 3.2). For the determination of $\delta^{18}\text{O}_{\text{equilibrium}}$, we used the general equations of *Mulitza et al.* [2004] that was developed using four foraminiferal species reflecting both surface and sub-surface species and the equation of *Kim and O'Neil* [1997] that was derived from inorganic calcite (see *Chapter 3.2.5*).

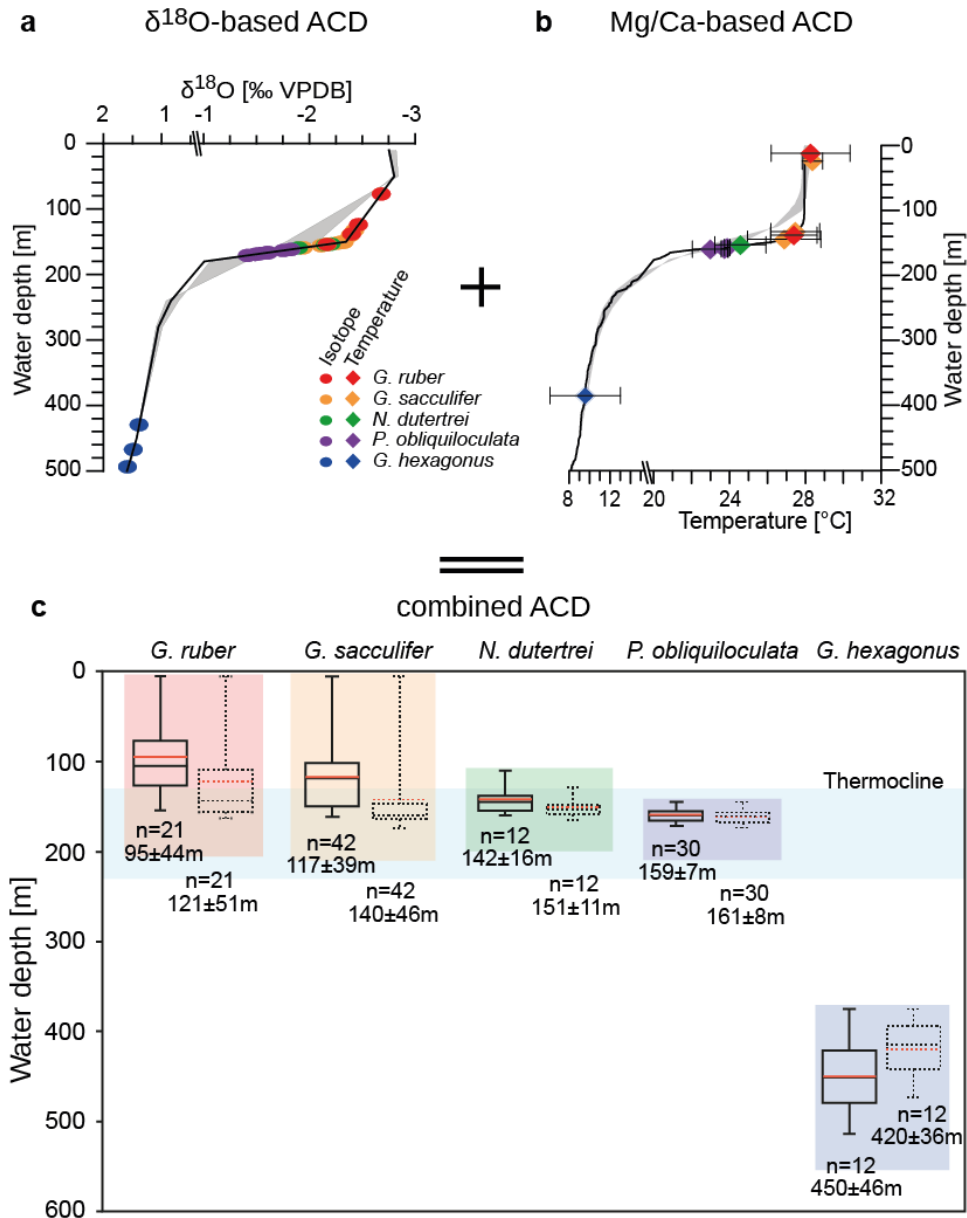

Figure 3.4. Assessment of Apparent Calcification Depths (ACD) for selected color-coded planktonic foraminiferal species from multinet station SO225-21. ACD is inferred from two approaches: a: measured foraminiferal $\delta^{18}\text{O}_{\text{calcite}}$ values were compared to $\delta^{18}\text{O}_{\text{equilibrium}}$ values, which were calculated using the water temperatures during sampling time (black) and seasonal temperatures [grey, *Locarnini et al.*, 2013] (see *Chapter 3.2.5* for detailed information), b: Mg/Ca derived species-specific temperature (with standard deviations) estimates were placed at water depths with the corresponding *in-situ* measured austral summer temperatures [*Werner et al.*, 2013] and seasonal temperature range [grey; *Locarnini et al.*, 2013] (see *Chapter 3.2.5*). c: Combined ACDs for each species. Each box plot represents the ACD of one species; the dashed box represents the ACD of each species corrected for $\delta^{18}\text{O}$ -disequilibrium effects. Each box comprises 50 % of determined ACDs, ranging from quartile Q 0.25 to Q 0.75. The two lines within the box mark the median (black line) and the mean (red line, values and standard deviation is given below the box plot) and allow to decipher the skewness of the ACD distribution. The whiskers (vertical lines) denote the minimum and maximum values. The number of measurements (n) is given below the box plot.

3.3.3.1 Apparent calcification depths of *G. ruber* and *G. sacculifer*

At multinet station SO225-21-3, *G. ruber* and *G. sacculifer* calcified over a broad depth range ranging from the sea surface down to ~160 m water depth (Figure 3.4, Table 3.3). This mirrors the thick SML in the WPWP and supports the notion of these species being surface-dwellers [Fairbanks *et al.*, 1982; Bé *et al.*, 1985; Ravelo and Fairbanks, 1992; Watkins *et al.*, 1996; Steph *et al.*, 2009; Rincón-Martínez *et al.*, 2011; Lynch-Stieglitz *et al.*, 2015; Nürnberg *et al.*, 2015].

Most studies point to a habitat of *G. ruber* within the first 30 m of the water column [Fairbanks *et al.*, 1982; Bé *et al.*, 1985; Faul *et al.*, 2000; Mohtadi *et al.*, 2009] and *G. sacculifer* within the first 80 m [Fairbanks *et al.*, 1982; Bé *et al.*, 1985; Watkins *et al.*, 1996; Steph *et al.*, 2009]. Our study revealed that in December 2012, highest *G. ruber* abundances were found in the nets of 50 – 100 m (Figure 3.3) and the ACD estimate showed that 50 % of *G. ruber* calcified between 70 and 125 m (Figure 3.4). The depth agrees well to the optimum temperature preference of ~27°C [Mulitza *et al.*, 1998]. Various studies point towards varying calcification depths for different morphotypes of *G. ruber* [Wang, 2000; Steinke *et al.*, 2005; Kuroyanagi *et al.*, 2008] and a seasonal bias in *G. ruber* abundances [e.g. Kawahata *et al.*, 2002; Stott *et al.*, 2002; Lin *et al.*, 2004; Žarić *et al.*, 2005]. However, with the present dataset we are not able to address this issue.

The determined ACDs of *G. sacculifer* are commonly deeper than the ACDs of *G. ruber* (Table 3.3), which corroborates Central Pacific core-top studies that recorded heavier $\delta^{18}\text{O}$ values and thus, a generally deeper ACD for *G. sacculifer* in comparison to *G. ruber* [Lynch-Stieglitz *et al.*, 2015]. Furthermore, a plankton tow study from the South Atlantic revealed that in areas with a thick mixed layer, *G. sacculifer* often exhibits deeper ACDs than *G. ruber*, whereas in areas with a shallow thermocline, both species dwell at similar depths [Kemle-von Mücke and Oberhänsli, 1999]. This observation agrees with the slightly cooler optimum temperature range in *G. sacculifer* compared to *G. ruber* [Bijma *et al.*, 1990]. Fifty percent of *G. sacculifer*'s ACDs fall in the depth range between 100 and 150 m, which is deeper than the highest abundances of this species, which is found in the nets in 0 – 50 m. However, it has been shown that *G. sacculifer* migrates to deeper water depths later in its ontogeny [Hemleben and Bijma, 1994]. As small individuals outnumber larger specimens due to the high mortality rate, highest total abundances of this species are much shallower than ACDs determined on larger specimens [Hemleben and Bijma, 1994]. Furthermore, a stratified plankton-tow study from the Red Sea showed that specimens from the 350 – 500 μm size fraction accumulate in a narrow depth range [Bijma and Hemleben, 1994] similar to our results. This also explains why tests selected from deeper habitats depths (100 – 200 m for *G. sacculifer* and 300 – 500 m for *G. ruber*) also record ACDs within the SML and not from the net depth range they were selected from (Tables 3.1 and 3.3). Hence, calcification of these tests happened within the SML. Just before net sampling, these specimens possibly died and sank down to the depth in which we caught them.

The SML at the study site extended deeper than the SML recorded by the long-term average at the same position (Figure 3.2a). This could explain why the ACDs of *G. ruber* and *G. sacculifer*

are deeper than ACDs estimated from seasonally varying temperatures (Table 3.3). Using seasonal temperatures, both species record shallowest ACDs in austral winter and deepest during austral summer, possibly also as a result of changes in the depth of the DCM (Figure 3.1c). Despite the fact that both species host symbionts and are therefore highly dependent on light availability [Hemleben and Bijma, 1994; Schiebel and Hemleben, 2005], the data suggest that these species possibly descend to deeper waters in oligotrophic environments to exploit the DCM for food as proposed by e.g. Fairbanks *et al.* [1982], Schiebel *et al.* [2001], Schiebel and Hemleben [2005], and Steph *et al.* [2009].

Species-specific vital-effects can alter the ACD assessment, as the deviation from isotopic equilibrium might result in too-deep or too-shallow calculated ACDs. In symbiont-bearing species vital effects have been shown to be large [Niebler *et al.*, 1999]. Correcting the measured $\delta^{18}\text{O}_{\text{calcite}}$ data for a disequilibrium of -0.4 ‰ and -0.6 ‰ [Niebler *et al.*, 1999] for *G. ruber* and *G. sacculifer*, respectively, results in <23 % deeper ACDs for *G. ruber* and <10 % deeper ACDs for *G. sacculifer* that would point to a calcification within the thermocline (Figure 3.4, Supplement Table S3.5.3). However, as the highest abundances of these species were found in surface waters similar to other studies, we find these deep vital-corrected ACDs rather unlikely.

In summary, it seems that ACDs determined by using measured temperatures during sampling (December 2012) or seasonal temperatures do not differ substantially. However, using vital-corrected ACDs might lead to different results as foraminifera might be placed into different water masses. Thus, to make realistic ACD-reconstructions, one needs to consider the combination of determined ACD, the local hydrography, local foraminiferal abundance data, and to take into account that the last few chambers determine the majority of the chemical signature of the shell.

3.3.3.2 Apparent calcification depths of *N. dutertrei* and *P. obliquiloculata*

The ACD assessment at the sampling site for *N. dutertrei* and *P. obliquiloculata* reveals calcification in a very narrow depth range at the top and within the upper thermocline, which is in broad agreement with ACD studies [e.g. Ravelo and Fairbanks, 1992; Faul *et al.*, 2000; Regenberg *et al.*, 2009; Steph *et al.*, 2009]. The mean ACD of $\sim 140 \pm 16$ m (*N. dutertrei*) and $\sim 160 \pm 7$ m (*P. obliquiloculata*) (Table 3.3) are somewhat deeper than in other studies, possibly due to the comparatively deep thermocline in the western equatorial Pacific. As the thermocline was warmer during sampling than the long-term average (see Chapter 3.3.1), we also calculated the ACDs using seasonal temperature data [Locarnini *et al.*, 2013]. The estimated seasonal ACDs are, however, within the ACD range determined by the combined stable isotope and temperature approach (Table 3.3). Furthermore, both species are also affected by isotopic disequilibrium. Correcting the measured $\delta^{18}\text{O}_{\text{calcite}}$ values of *N. dutertrei* and *P. obliquiloculata* for disequilibrium of -0.2 ‰ and -0.1 ‰ [Niebler *et al.*, 1999], respectively, only small shifts towards

deeper water depths of <3 % for *N. dutertrei* and <1 % for *P. obliquiloculata* occur (Figure 3.4; Supplement Table S3.5.3).

The net collection from this study has the highest abundance of *N. dutertrei* in 50 – 100 m water depth within the DCM (Figure 3.3). This agrees with the general view that *N. dutertrei* inhabits a shallow water depth close to the DCM [Fairbanks *et al.*, 1982; Bé *et al.*, 1985; Hemleben *et al.*, 1989; Ravelo and Fairbanks, 1992; Dekens *et al.*, 2002; Schmuker and Schiebel, 2002; Sadekov *et al.*, 2013]. Our study site at the Manihiki Plateau is at the border of the Pacific Equatorial Divergence (see also Chapter 3.3.2). As the longitudinal transition between WPWP and Pacific Equatorial Divergence varies between ~150°E and 150°W [Le Borgne *et al.*, 2002] depending on the wind strength and surface currents, it is expected that *N. dutertrei* changes its habitat and calcification depth depending on the prevailing environmental setting. This is supported by calcification-depth studies from the highly dynamic eastern equatorial Pacific that reveal variable habitats depending on the strength of the coastal upwelling with shallower habitats in cases of strong upwelling [Nürnberg *et al.*, 2015, and discussion therein].

Our ACD estimates for *P. obliquiloculata* correspond well with the observations: all specimens, regardless of the net depth the foraminifera were taken from, calcified between 145 m and 170 m and highest abundances of adult specimen were found in nets of 100 – 200 m water depths. Consequently, this species might be more appropriate for thermocline reconstructions. This is in line with previous studies showing that *P. obliquiloculata* is associated with the base of the upper thermocline in other ocean basins [e.g. Ravelo and Fairbanks, 1992; Faul *et al.*, 2000; Mohtadi *et al.*, 2009; Rincón-Martínez *et al.*, 2011].

3.3.3.3 Apparent calcification depths of *G. hexagonus*

Both $\delta^{18}\text{O}$ -derived and Mg/Ca-derived ACDs display a deep habitat for *G. hexagonus* ranging from 375 to 515 m water depth (mean ACD: 450 m \pm 46 m) (Figure 3.4, Table 3.3) below the thermocline. As seasonal temperature variations are <0.4°C in 300 – 500 m water depth, the ACD of *G. hexagonus* varies by maximal 30 m. Most deep-dwelling foraminifera calcify close to isotopic equilibrium with small positive deviations [Niebler *et al.*, 1999]. Applying a +0.1 ‰ disequilibrium-correction to the $\delta^{18}\text{O}_{\text{calcite}}$ values (Supplement Table S3.5.3) results in an up to 30 m shallower ACD, which is still clearly below the thermocline (Figure 3.4). Overall, the assessed ACDs correspond well to the highest abundances from the net collection in 300 – 500 m water depth (Figure 3.3).

Depth assignments from other studies are rare, as this species is endemic for the Indo-Pacific [Schiebel and Hemleben, 2005] and hardly ever exceeds a relative abundance of 2 % in sediment assemblages [Beiersdorf *et al.*, 1996; Hilbrecht, 1996]. Our depth assessment, nevertheless, is similar to a study from the North Pacific with an estimated calcification depth of 330 – 390 m below the thermocline [Ortiz *et al.*, 1996]. However, our estimated ACD is deeper than the calcification depth reported from a core-top study from the western tropical Indian Ocean

that places the calcification depth between ~100 – 160 m, i.e. within the mid-thermocline [Birch *et al.*, 2013]. These differences are probably the result of an interaction of four different effects:

1) In the Indian Ocean, Birch *et al.* [2013] used a different size window ranging from 125 to 300 μm , whereas the test selected for this study range from 250 to 400 μm . Although smaller individuals often inhabit shallower waters than larger individuals [Fairbanks *et al.*, 1982; Bijma and Hemleben, 1994; Kroon and Darling, 1995], our smallest size fraction still records far deeper habitats than largest specimen derived from Indian Ocean samples. Thus, the size effect on the different ACDs is assumed to be rather small.

2) Birch *et al.* [2013] applied the paleotemperature equation of Erez and Luz [1983], which was calibrated using symbiont-bearing *G. sacculifer*. As *G. hexagonus* does not harbour symbionts [Parker, 1962], this symbiotic equation may result in erroneous temperatures. Symbionts increase ambient pH and $[\text{CO}_3^{2-}]$ and hence decrease shell $\delta^{18}\text{O}$ [Spero *et al.*, 1997; Bijma *et al.*, 1999], leading to an over-estimation of the real calcification temperature and hence would infer a calcification depth that is too shallow. By recalculating the ACD of *G. hexagonus* in the Indian Ocean with the equation by Kim and O'Neil [1997], the resulting ACD is deeper, between 110 and 180 m. Nevertheless, this re-calculated ACD still lies within the western tropical Indian Ocean thermocline, highlighting the need for further explanations for varying ACDs of *G. hexagonus*.

3) Ortiz *et al.* [1996] argue that *G. hexagonus* is a sub-thermocline species well adapted to its deep habitat, which is associated with the NPIW in the North Pacific. This water mass is characterized by elevated nutrient and particulate organic matter concentrations [e.g. Yamanaka and Tajika, 1996; Sarmiento *et al.*, 2004]. In contrast, sub-thermocline Indian Ocean water masses are less nutrient-rich than in the North Pacific. Furthermore, deep-dwelling (non-spinose) foraminifera such as *Globorotalia tuncatulinoides* or *Globorotalia hirsuta* are mainly herbivores [Hemleben *et al.*, 1989; Schiebel and Hemleben, 2005]. The sub-thermocline species *Globorotalia scitula*, for example, feeds on detrital, particulate organic material [Itou *et al.*, 2001]. As *G. hexagonus* inhabits a similar depth range to that of *G. tuncatulinoides* and *G. scitula*, we hypothesize that *G. hexagonus* is also a herbivore, feeding on particulate organic material. Consequently, *G. hexagonus* possibly calcifies in shallower water masses in the western Indian Ocean within the thermocline, where nutrients and particulate organic material accumulate. At our sampling site, the majority of Pacific equatorial sub-surface waters originate from outside the tropics and feed the equatorial sub-surface current system. The ACD determined for *G. hexagonus* corresponds to the depth of the Tsuchiya Jets that transport nutrients and particulate organic material originating in the extra-tropical regions along the equatorial Pacific (Figure 3.1a) [Johnson and Moore, 1997; Rowe *et al.*, 2000]. Thus, we conclude, that *G. hexagonus* favours water masses enriched in nutrients.

4) Another important factor might be the insensitivity of *G. hexagonus* to changing oxygen concentrations in the water column [Birch *et al.*, 2013]. In the Indian Ocean, *G. hexagonus*

calcifies in relatively low oxygen concentrations of 100 – 130 $\mu\text{mol/kg}$, just above the OM [Birch *et al.*, 2013]. Similarly, at our sampling site, the ACDs in 375 – 500 m water depth correspond to decreasing oxygen concentrations ($\sim 60 \mu\text{mol/kg}$) (Figure 3.2d) towards the OM at 450 m water depth. Hence it seems, that *G. hexagonus* prefers to calcify in cool, oxygen-depleted and nutrient-rich water masses and consequently, might be most suitable for reconstructing the variability in extra-tropical nutrient inflow into the equatorial current system.

3.3.4 Foraminiferal carbon isotope disequilibrium

In order to evaluate modern species-specific $\delta^{13}\text{C}$ -disequilibrium effects at certain growth stages, we measured the $\delta^{13}\text{C}_{\text{calcite}}$ values on various size fractions. The overall $\delta^{13}\text{C}_{\text{calcite}}$ values range from -0.14‰ in *N. dutertrei* to a maximum value of $+1.53 \text{‰}$ in *G. sacculifer* (Figure 3.5, Table 3.4). Generally, deeper dwelling species record lower $\delta^{13}\text{C}_{\text{calcite}}$ values (concomitant with higher $\delta^{18}\text{O}_{\text{calcite}}$ values) than SML species. A variety of parameters including algal photosynthesis [Bé *et al.*, 1982; Hemleben *et al.*, 1989], metabolic fractionation [Wefer and Berger, 1991; Kroon and Darling, 1995; Spero *et al.*, 1997], food availability [Spero *et al.*, 1991; Ortiz *et al.*, 1996], and carbonate chemistry of the seawater [Spero *et al.*, 1997; Bijma *et al.*, 1999] influence foraminiferal $\delta^{13}\text{C}_{\text{calcite}}$ values.

Figure 3.5. Measured $\delta^{13}\text{C}_{\text{calcite}}$ of selected living planktonic foraminifera in comparison to the *in-situ* measured $\delta^{13}\text{C}_{\text{DIC}}$ (black line) measured at multinet station SO225-21-3. Each symbol corresponds to a single species. The size of the symbol characterizes the specific test-size spectrum. Instrumental standard deviation is smaller than symbol sizes ($\pm 0.01 \text{‰}$), therefore not shown. Coloured-boxes

illustrate the depths at which 50 % of each species calcify (Figure 3.4c). Values more negative than the equilibrium line are mostly affected by metabolism and respired light carbon, more positive values are possibly affected by symbiotic activity. Grey shaded area represents the ± 0.5 ‰ inter-sample $\delta^{13}\text{C}_{\text{calcite}}$ variability ($\delta^{13}\text{C}_{\text{calcite}}$ -envelope') expected in foraminiferal analyses.

Table 3.4. Foraminiferal $\delta^{13}\text{C}_{\text{calcite}}$ values with the determined $\delta^{13}\text{C}$ -disequilibrium and $\delta^{13}\text{C}$ -disequilibrium values using vital-corrected ACDs. Each line represents one measurement of the respective species.

| Species | Shell size [range in μm] | Number of tests measured | $\delta^{13}\text{C}_{\text{calcite}}$ [‰] | Disequilibrium [‰] | Disequilibrium 'vital-corrected' [‰] |
|---------------------------|--------------------------------------|--------------------------|--|--------------------|--------------------------------------|
| <i>G. ruber</i> | 150 – 250 | 18 | -0.04 | -1.1 | -0.9 |
| | 150 – 250 | 17 | 0.02 | -1.0 | -0.9 |
| | 250 – 300 | 11 | 0.71 | -0.3 | -0.2 |

| | >500 | 3 | 0.99 | 0.3 | 0.3 |
| | >500 | 2 | 1.29 | 0.6 | 0.6 |
| <i>N. dutertrei</i> | 250 – 300 | 12 | -0.14 | -0.9 | -0.9 |
| | 300 – 350 | 9 | -0.08 | -0.9 | -0.8 |
| | 350 – 500 | 6 | 0.03 | -0.8 | -0.7 |
| <i>P. obliquiloculata</i> | 350 – 500 | 4 | 0.06 | -0.7 | -0.7 |
| | 350 – 500 | 4 | -0.01 | -0.7 | -0.7 |
| | >500 | 2 | -0.01 | -0.7 | -0.7 |
| | >500 | 2 | 0.26 | -0.5 | -0.5 |
| | >500 | 2 | 0.25 | -0.5 | -0.5 |
| | >500 | 2 | 0.11 | -0.6 | -0.6 |
| <i>G. hexagonus</i> | >500 | 2 | 0.41 | -0.3 | -0.3 |
| | 250 – 300 | 10 | -0.06 | -0.5 | -0.5 |
| | 300 – 350 | 9 | 0.22 | -0.2 | -0.2 |
| | 350 – 500 | 6 | 0.24 | -0.2 | -0.2 |

Using the determined ACDs in which 50 % of the species calcify (between quartile Q 0.25 and Q 0.75) (Figure 3.4c), we attempted to infer the species-specific $\delta^{13}\text{C}$ -disequilibrium from ambient seawater at the study site. We did not determine the carbonate chemistry at the study site and

hence, we cannot correct for the carbonate ion effect. Nevertheless, the measured $\delta^{13}\text{C}_{\text{calcite}}$ reveals a distinct size-dependent deviation from $\delta^{13}\text{C}_{\text{DIC}}$ values that generally agrees with other studies, such as *Oppo and Fairbanks* [1989], *Spero et al.* [1991], *Spero and Lea* [1993], *Kroon and Darling* [1995], and *Birch et al.* [2013]. The offset from ambient seawater for most species is even more pronounced than the added $\pm 0.5\text{‰}$ $\delta^{13}\text{C}$ -uncertainty (the ' $\delta^{13}\text{C}$ -envelope') that might be expected in measured foraminiferal values to account for inter-sample variability expected in foraminiferal analysis [*Birch et al.*, 2013]. We also used 'vital-effect' corrected ACDs for the $\delta^{13}\text{C}$ -disequilibrium assessment. However, following this approach only results in little, if any, change in the ACD of the respective species (Table 3.4).

Large individuals of symbiont-bearing *G. ruber* and *G. sacculifer* are influenced by algal photosymbiosis. The symbionts preferentially incorporate light carbon into the organic matter leaving the microenvironment the foraminifera calcifies from enriched in ^{13}C . Hence, ^{13}C -enriched chambers are produced [*Spero and Lea*, 1993]. Since the symbiont density increases with shell size [*Spero and Parker*, 1985], the $\delta^{13}\text{C}_{\text{calcite}}$ values become more positively offset from ambient seawater $\delta^{13}\text{C}_{\text{DIC}}$ with up to $+0.8\text{‰}$ in *G. sacculifer*. However, small individuals of SML and thermocline species have a large surface-to-volume ratio, tend to grow more rapidly, and possibly show a larger impact of depleted, respired CO_2 due to higher metabolic activity [*Berger et al.*, 1978; *Wefer and Berger*, 1991; *Spero et al.*, 1997]. As a result, foraminiferal $\delta^{13}\text{C}_{\text{calcite}}$ is often negatively offset from equilibrium by up to -1.1‰ (in *G. ruber*) (Table 3.4). As an individual grows, the influence of symbiont-isotopic fractionation increases and dominates over the impact of respiration [*Berger et al.*, 1978; *Wefer and Berger*, 1991; *Spero et al.*, 1997].

Deep-dwelling asymbiotic *G. hexagonus* generally reveals a disequilibrium fractionation of $\leq -0.5\text{‰}$, which is in the range of the $\delta^{13}\text{C}_{\text{DIC}}$ -uncertainty. Only small tests of this species are slightly negatively depleted in $\delta^{13}\text{C}_{\text{calcite}}$, probably due low metabolic rates as a consequence of low temperatures. Nevertheless, the near-equilibrium calcification is supported by a study from the tropical Indian Ocean [*Birch et al.*, 2013], highlighting *G. hexagonus* as a reliable recorder of $\delta^{13}\text{C}$ in sub-surface water masses.

3.4 Conclusions

The quality of paleoceanographic reconstructions of upper-ocean water mass conditions is tied to our precise knowledge of the ACDs of the studied foraminiferal species. The comparison between $\delta^{18}\text{O}_{\text{calcite}}$ and Mg/Ca-derived temperatures measured on five living planktonic species with *in-situ* physical and chemical water mass properties enables us to enhance our knowledge about the species-specific ACDs.

The WPWP experiences a pronounced year-round thick SML that still extends deeper during December 2012 down to ~ 130 m water depth. Determined ACDs of symbiont-bearing species *G. ruber* and *G. sacculifer* using both seasonal temperature data and temperatures during

sampling indicate mean calcification depth of ~95 m and ~120 m, respectively, corresponding to the base of the SML. These ACDs are deeper than in other ocean basins due to the hydrographic conditions of the WPWP, and the optimum temperature preference of these foraminifera. As vital effects further affect symbiont-bearing species, a combined approach of foraminiferal abundances, determined ACDs and hydrography provides most reliable ACD reconstructions.

Below the SML *N. dutertrei* and *P. obliquiloculata* calcified in a very narrow depth range of 140 – 160 m, corresponding to the top and within the thermocline, regardless of the temperature data used (seasonal or during sampling). The same holds true for vital effect corrections. The agreement between our ACD of *P. obliquiloculata* and other studies, suggest that *P. obliquiloculata* is most suitable for thermocline reconstructions.

The species *G. hexagonus* records mean ACDs of ~450 m and is thus the deepest dwelling species from the analysed species of this study. It calcifies its test in oxygen-depleted, but nutrient-rich water masses. The same trend has been observed in other studies from different ocean basins. Temperature and seawater chemistry are more stable in sub-surface waters compared to surface water conditions. As a consequence, *G. hexagonus* calcifies in $\delta^{13}\text{C}$ -equilibrium with ambient seawater, and hence, this species serves as an archive for tracing nutrient variations in equatorial Pacific mode and intermediate water masses being sourced in extra-tropical regions.

S3.5.3. Evaluation of various Mg/Ca-temperature calibrations

Mg incorporation into foraminiferal tests is highly biologically mediated [Nürnberg *et al.*, 1996; Rosenthal *et al.*, 1997; Lea *et al.*, 1999; Dueñas-Bohórquez *et al.*, 2009; 2011]. Due to these so-called “vital effects” there are species-specific differences in the uptake of Mg into the foraminiferal calcitic test. As a consequence, separate Mg/Ca thermometer calibrations for different species of planktonic foraminifera have been developed either on core top samples or culture experiments [Nürnberg *et al.*, 1996; Dekens *et al.*, 2002; Anand *et al.*, 2003; Cléroux *et al.*, 2008; Regenberg *et al.*, 2009]. All equations have basic similarities, but slight differences might lead to significantly different temperatures estimates when applied to the same Mg/Ca ratio. To find the most applicable calibration equation for each investigated planktonic foraminiferal species from the multinet samples, we converted the measured foraminiferal Mg/Ca ratios into temperatures using generic and species-specific equations if available (Table S3.5.3, Figure S3.5.3). We analysed as many chambers as possible to minimize random variations in Mg/Ca within a test [de Nooijer *et al.*, 2014]. Previous culturing studies have investigated the difference between whole-test calibrations and Mg/Ca-temperature equations based on Mg/Ca measurements of the last four chambers and found no significant difference between them [Dueñas-Bohórquez *et al.*, 2009; Spero *et al.*, 2015]. Further, Hathorne *et al.* [2003] and Reichert *et al.* [2003] found that Mg/Ca data from both single-chamber and multiple-shells are similarly correlated to temperature. At the depth interval in which a species was found in highest abundance per m³ at the Manihiki Plateau (Table S3.5.1), we determined the mean temperature during sampling time from both CTD data and the seasonal range in temperature from the WOA13 data [Locarnini *et al.*, 2013] at the same location. By comparing these *in-situ* temperatures with the Mg/Ca-derived temperatures, we identified the most suitable calibration equation for each species at our study site.

G. sacculifer was found most abundant per m³ in 0 – 100 m water depth. The calibration of Anand *et al.* [2003] gives the warmest temperatures, which are consistently higher than the seasonal range and result in temperatures of up to 32°C. A similar result derives using the equation by Nürnberg *et al.* [2000]. Thus, we neglect these calibrations. Using the calibration by Dueñas-Bohórquez *et al.* [2011, whole chamber] results in coldest temperature. The temperatures derived by Dekens *et al.* [2002] deviate from the average temperatures by only up to 0.8°C. As this calibration was deduced using surface sediment samples from the equatorial Pacific, we found this equation most applicable for our *G. sacculifer* calibration.

G. ruber is analysed frequently in paleoceanographic research to reconstruct past sea surface temperatures, hence many species-specific calibrations are available. The net collections indicate that *G. ruber* appears most abundant per m³ in water depths between 0 – 100 m. The comparison between the calculated and *in-situ* temperatures from that depth interval shows that the species-specific calibration of Lea *et al.* [2000] results in the warmest temperatures of >30°C, which outreaches the *in-situ* temperatures and the seasonal range by far. Thus, we reject this

calibration curve to minimize an overestimation of our temperatures. The calibration of *Mohtadi et al.* [2009] gives the coldest temperatures for *G. ruber*, even colder than the seasonal temperature range. Calibration equations of *Dekens et al.* [2002], *Regenberg et al.* [2009], and *Anand et al.* [2003] are similar and differ only by $\sim 1^\circ\text{C}$. Both *Dekens et al.* [2002] and *Regenberg et al.* [2009] calibrated their equation with material from the low latitudes. As *Regenberg et al.* [2009] used *G. ruber* shells from a similar size fraction (355 – 400 μm) as our analysed foraminifera (320 – 425 μm), we selected this species-specific calibration equation for further analyses of *G. ruber*.

Neogloboquadrina dutertrei and *P. obliquiloculata* were both found in major abundances per m^3 between 50 – 100 m water depth. However, we compared the Mg/Ca-derived temperatures to *in-situ* temperatures from 100 – 200 m water depth, as most large foraminifers of these species were found at this depth. As this depth interval collides with the thermocline, a very large seasonal range exists. For *N. dutertrei* we applied three species-specific and one generic calibration equation. The various calibrations show a large scatter within the calculated temperature with coldest temperatures derived from *Elderfield and Ganssen* [2000] and warmest temperatures with the equation of *Anand et al.* [2003]. *Elderfield and Ganssen* [2000] used a combination of 8 different species for its equation and thus, is not species-specific. We also reject the calibration of *Dekens et al.* [2002], despite the fact that the calculated temperatures lies well within the seasonal range. However, *Dekens et al.* [2002] assumed for its equation a habitat depth of their adult species of 50 m for *N. dutertrei*. Due to the varying habitat of this species [e.g. *Nürnberg et al.*, 2015], the authors itself denote the limit of their equation for *N. dutertrei*. Most applicable for our *N. dutertrei* Mg/Ca estimates is the calibration of *Regenberg et al.* [2009]. This calibration yields temperatures most similar to the mean temperature between 100 – 200 m water depth.

For *P. obliquiloculata* we tested two species-specific equations and additionally consulted two generic equations. The species-specific calibration of *Cléroux et al.* [2008] results in very high temperatures. This calibration was developed using core-top samples from the North Atlantic. Further the derived temperatures of up to 29°C outreach even the seasonal range of sea-surface temperatures of $27.8 - 28.4^\circ\text{C}$. Thus, this equation was discarded. The *Elderfield and Ganssen* [2000] calibration reveals the coolest temperatures. Although these calculated temperatures are within the seasonal range of the temperatures at 100 – 200 m water depth, it is far colder than the mean temperature at 100 – 200 m water depth in December 2012. The equations of *Anand et al.* [2003] and the ‘warm-water’ species calibration of *Regenberg et al.* [2009] seem more promising. Both are very similar and differ only by $\sim 0.3^\circ\text{C}$. Unfortunately, *Regenberg et al.* [2009] did not analyse *P. obliquiloculata*. The applied calibration is a combination of three warm-water species (*G. ruber* pink and white, *G. sacculifer*) and two species associated with the thermocline (*G. menardii* and *N. dutertrei*). All these foraminifers are thought to host symbionts [*Kucera*, 2007], while *P. obliquiloculata* is only facultative symbiotic [*Hemleben et al.*, 1989]. Hence, we apply the species-specific calibration of *Anand et al.* [2003] for the *P. obliquiloculata* analyses.

No species-specific calibration exists for the Indo-Pacific species *G. hexagonus* so far. *G. hexagonus* was found most frequently in nets of 300 – 500 m water depth. The mean temperatures in this depth interval is 9.4°C. Using the general calibration of *Anand et al.* [2003], which was calibrated by using 10 planktonic species, reveals the warmest temperatures of 14.2°C. Similar to *G. hexagonus*, *G. truncatulinoides* is frequently hauled from deep waters below the thermocline [*Hemleben et al.*, 1989]. Therefore, we also applied the species-specific equation of *G. truncatulinoides* [*Anand et al.*, 2003] to our *G. hexagonus* Mg/Ca values. However, this results in even higher temperatures of 14.8°C. As a consequence, we reject both equations. We further tested a *G. bulloides* equation from the North Atlantic [*Cléroux et al.*, 2008] as both *G. hexagonus* and *G. bulloides* are symbiont-barren [*Hemleben et al.*, 1989], and the ‘cold-water’ species equation of *Regenberg et al.* [2009]. Both Mg/Ca calculated temperatures are colder than the mean and seasonal temperatures at the Manihiki Plateau. *Regenberg et al.* [2009] used a mixture of the deep-dwelling foraminifera *G. truncatulinoides* and *G. crassaformis* for their ‘cold-water’ equation. During their ontogeny both *G. truncatulinoides* and *G. crassaformis* sink to deeper water depths and build a thick calcite crust that reflects the colder waters [*Schiebel and Hemleben*, 2005]. This might be the reason for the colder temperatures calculated from our *G. hexagonus* Mg/Ca values. Most suitable for our calculation is the general calibration of *Elderfield and Ganssen* [2000]. The eight planktonic species used for this calibration mirror the broad range of foraminiferal habitats. The resulting calculated temperature of 9.6°C fit well with our measured mean *in-situ* temperature of 9.4°C and is therefore assumed to be the most suitable calibration for the *G. hexagonus* Mg/Ca values from the Manihiki Plateau.

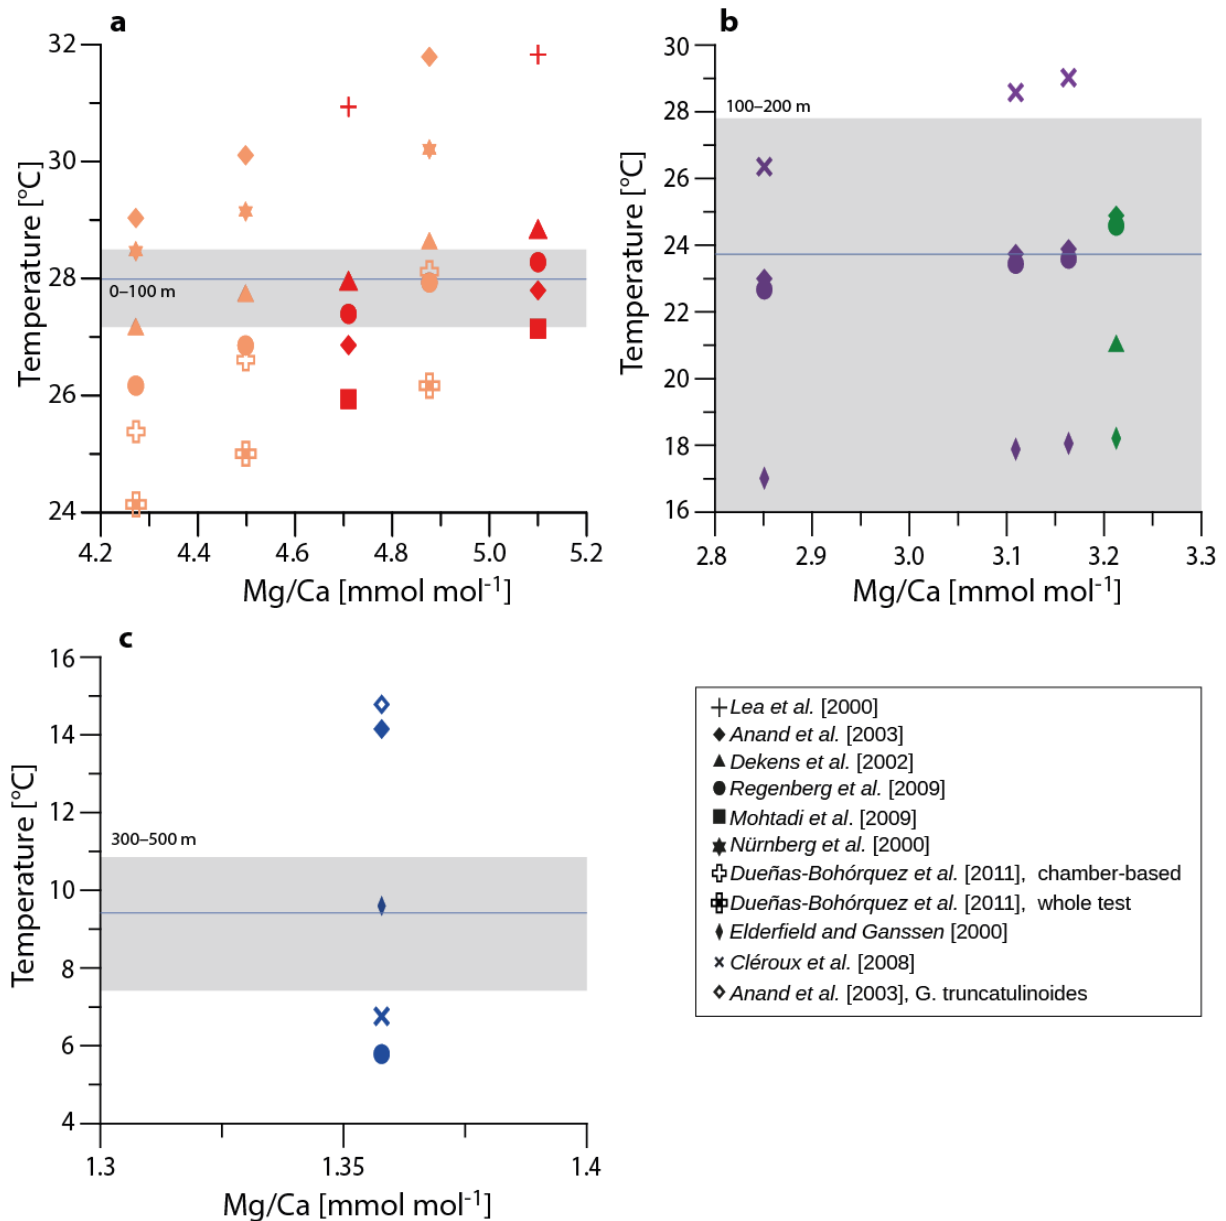

Figure S3.5.3. Foraminiferal Mg/Ca derived temperatures for mean Mg/Ca values determined over a whole test using various calibration equations for a: *G. sacculifer* (orange) and *G. ruber* (red), b: *P. obliquiloculata* (purple) and *N. dutertrei* (green), and c: *G. hexagonus* (blue). Each vertical sequence of symbols denotes one specimen whereas each symbol represents a different calibration equation from various authors (see also Table S3.5.3). The blue line represents the mean temperatures in December 2012 over the depth interval each foraminifera were found most abundant in the net collections. The grey bar shows the seasonal temperature range derived from the WOA13 Data [Locarnini et al., 2013].

¹MSD = maximum shell diameter

Table S3.5.4. Apparent Calcification Depths (ACDs) of selected planktonic foraminiferal species used in this study determined by the comparison between the measured oxygen isotope values ($\delta^{18}\text{O}_{\text{calcite}}$) with that theoretically expected at various water depths ($\delta^{18}\text{O}_{\text{equilibrium}}$) in dependence of temperature and salinity. $\delta^{18}\text{O}_{\text{equilibrium}}$ was calculated using $\delta^{18}\text{O}$ -paleotemperature equations of *Shackleton [1974]* (sha), *Bemis et al. [1998]* (bem), *Kim and O'Neil [1997]* (kim) and *Mulitza et al. [2004]* (mul). Seasonal data were taken from the World Ocean Atlas database [*Locarnini et al., 2013*]. To correct for disequilibrium effects, isotope values were corrected with disequilibrium values of -0.6 ‰ for *G. sacculifer*, -0.4 ‰ for *G. ruber*, -0.2 ‰ for *N. dutertrei* and -0.1 ‰ for *P. obliquiloculata*. Deep-dwelling foraminifera calcify close to equilibrium. For *G. hexagonus* we assume a calcification depth between *G. tumida* and *G. crassaformis* and hence corrected our values for a disequilibrium of +0.1 ‰. Mean and \pm standard deviation is given for each species and equation.

| Species | $\delta^{18}\text{O}_{\text{calcite}}$ [‰] | ACDs using | | | | seasonal ACDs after kim & mul | | disequilibrium corr. after |

S3.5.5: $\delta^{18}\text{O}_{\text{water}}$ calculation to validate combined ACD approach

The measured Mg/Ca data and $\delta^{18}\text{O}$ data enable us to calculate of the $\delta^{18}\text{O}$ of the water. The calculated $\delta^{18}\text{O}_{\text{water}}$ can be compared to the measured $\delta^{18}\text{O}_{\text{seawater}}$ (Figure 3.2c). This will enable us to further validate the combined ACD approach, if the calculated $\delta^{18}\text{O}_{\text{water}}$ values are close to the $\delta^{18}\text{O}_{\text{seawater}}$ curve. To calculate the $\delta^{18}\text{O}_{\text{water}}$, different paleotemperature equations were selected (Table S3.5.5) and rearranged for $\delta^{18}\text{O}_{\text{water}}$. Mean temperature from Mg/Ca and mean $\delta^{18}\text{O}_{\text{calcite}}$ of the respective species were inserted. The $\delta^{18}\text{O}_{\text{water}}$ was then compared to the measured $\delta^{18}\text{O}_{\text{seawater}}$. Figure S3.5.5 displays the calculated $\delta^{18}\text{O}_{\text{water}}$ of the respective species in comparison to the measured $\delta^{18}\text{O}_{\text{seawater}}$. It demonstrates that the calculated $\delta^{18}\text{O}_{\text{water}}$ mirrors the measured $\delta^{18}\text{O}_{\text{seawater}}$ curve.

Under review in Paleoceanography

Abstract

We provide high-resolution foraminiferal stable carbon isotope ($\delta^{13}\text{C}$) records from the subarctic Pacific and Eastern Equatorial Pacific (EEP) to investigate circulation dynamics between the extra-tropical and tropical North Pacific during the past 60 kyr. We measured the $\delta^{13}\text{C}$ composition of the epibenthic foraminiferal species *Cibicides lobatulus* (*C. lobatulus*) from a shallow sediment core recovered from the western Bering Sea (SO201-2-101KL; 58°52.52'N, 170°41.45'E, 630 m water depth) to reconstruct past ventilation changes close to the source region of Glacial North Pacific Intermediate Water (GNPIW). Information regarding glacial changes in the $\delta^{13}\text{C}$ of sub-thermocline water masses in the EEP is derived from the deep-dwelling planktonic foraminifera *Globorotaloides hexagonus* (*G. hexagonus*) at ODP Site 1240 (00°01.31'N, 82°27.76'W, 2921 m water depth). Apparent similarities in the long-term evolution of $\delta^{13}\text{C}$ between GNPIW, intermediate waters in the eastern tropical North Pacific and sub-thermocline water masses in the EEP suggest the expansion of relatively ^{13}C -depleted, nutrient-enriched, and northern-sourced intermediate waters to the equatorial Pacific under glacial condi-

ons. Further, it appears that additional influence of GNPIW to the tropical Pacific is consistent with changes in nutrient distribution and biological productivity in surface-waters of the glacial EEP. Our findings highlight potential links between North Pacific mid-depth circulation changes, nutrient cycling, and biological productivity in the equatorial Pacific under glacial boundary conditions.

4.1 Introduction

The high latitudes of the North Pacific and the Southern Ocean play an essential role in regulating the exchange of CO₂ between the ocean and the atmosphere [Takahashi *et al.*, 2002]. In both regions, vertical mixing brings nutrient- and CO₂-rich deep waters into the euphotic zone and facilitates the biological pump, which sequesters atmospheric CO₂ back into the deeper ocean interior [e.g. Honda *et al.*, 2002]. In the modern North Pacific, however, the further exposure of nutrient- and CO₂-rich sub-surface waters to the surface ocean is largely hampered by a permanent halocline [Haug *et al.*, 1999]. In both regions, intermediate water masses are formed that re-circulate excess nutrients from the high-latitude oceans towards the low latitude-regions of the Pacific Ocean (Figure 4.1). North Pacific Intermediate Water (NPIW) is formed in the sub-surface of the Northwest Pacific via mixing of high-nutrient sub-surface waters and intermediate water masses produced in coastal polynyas through brine rejection during wintertime sea-ice production in the Okhotsk Sea [Talley, 1993; Shcherbina *et al.*, 2003]. Today, NPIW circulates within the upper ~300 – 800 m and is mainly restricted to the subtropical North Pacific regions between ~20°N – 40°N, however a tongue of NPIW also spreads into the Celebes Sea in the western tropical Pacific [Talley, 1993; Bostock *et al.*, 2010]. In the Southern Ocean Antarctic Intermediate Water (AAIW) is produced at the surface ocean from upwelled nutrient- and CO₂-enriched Circumpolar Deep Water (CDW). AAIW ventilates into the Subtropical Gyre known as “ocean tunnelling” and thereby affects the equatorial current system (Figure 4.1). An important difference between northern- and southern-sourced intermediate waters is that sub-surface formation of NPIW largely prevents the biologically driven re-setting of deep ocean nutrient ratios that happens at the surface ocean during formation of AAIW. It is for this reason that NPIW is characterized by higher silicic acid to nitrate supply ratios compared to southern-sourced intermediate waters (Figure 4.1) [Sarmiento *et al.*, 2004]. On the other hand, as carbon fixation is dominated by siliceous phytoplankton at the surface-ocean near the formation region of modern AAIW, southern-sourced intermediate waters are characterized by high nitrate, but low silicic acid concentrations (Figure 4.1) [Sarmiento *et al.*, 2004].

Under modern conditions, mainly southern-sourced water masses (AAIW) are injected into the eastward-directed Equatorial Undercurrent (EUC) and the Equatorial Pacific Intermediate Water (EqPIW) via the South Equatorial Current and the New Guinea Coastal Undercurrent [Dugdale *et al.*, 2002]. The dominant role of AAIW on equatorial intermediate waters was also verified by a geochemical tracer analyses that suggests that EqPIW are primarily a combination of AAIW and

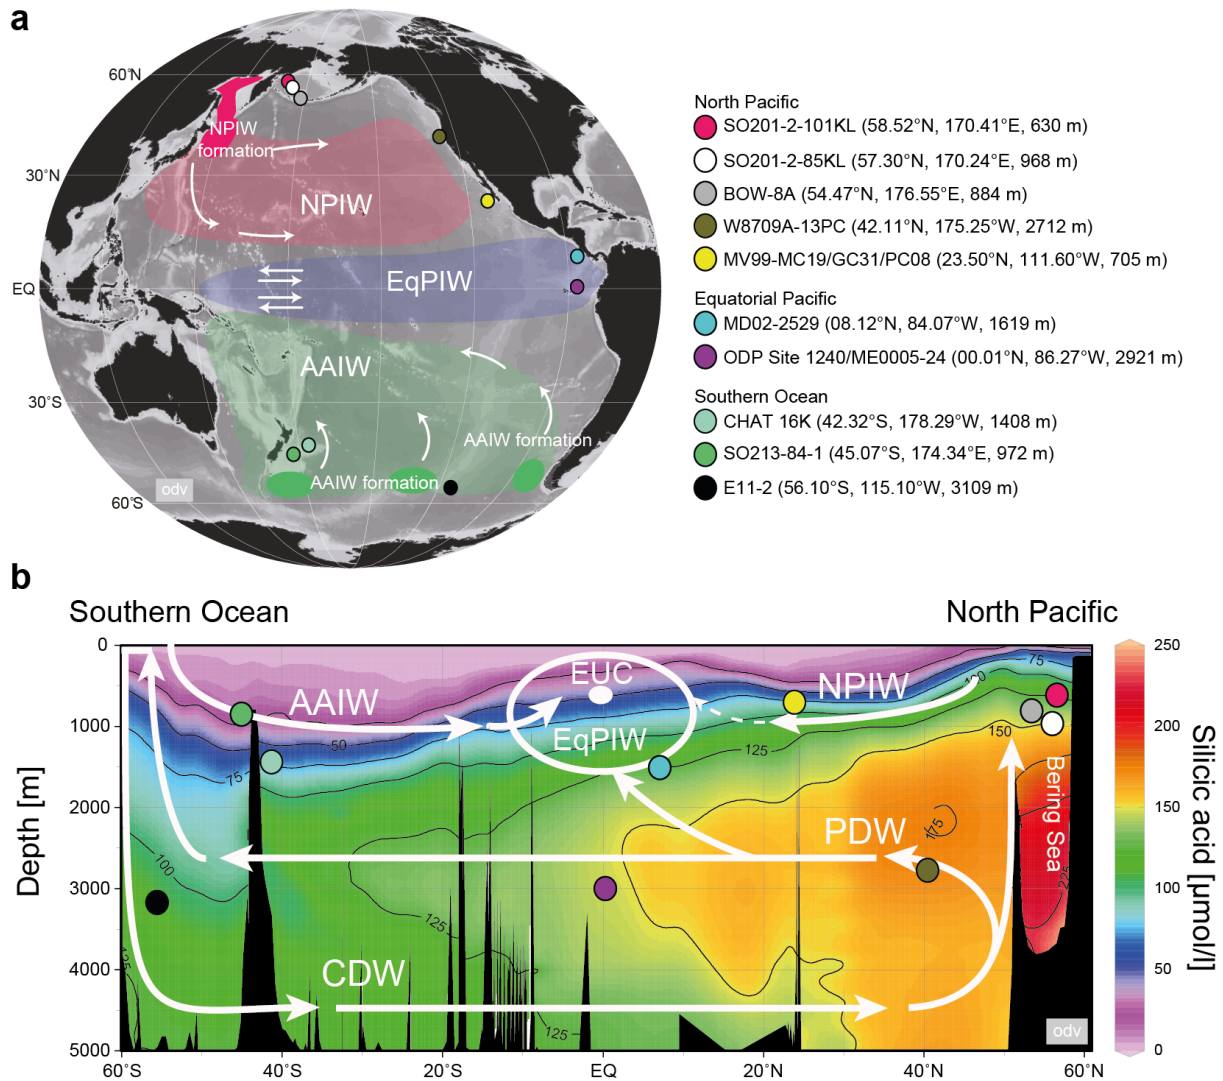

Figure 4.1. a: Bathymetric chart of the Pacific Ocean with locations of proxy records in the North Pacific (SO201-2-101KL, *this study*; SO201-2-85KL, *Max et al.*, 2012; BOW-8A, *Horikawa et al.*, 2010; W8709A-13PC, *Lund and Mix*, 1998; MV99-MC19/GC31/PC08, *Basak et al.*, 2010), the Equatorial Pacific (MD02-2529, *Leduc et al.*, 2010; ODP Site 1240, *Pichevin et al.*, 2009; *this study*; ME0005-24, *Kienast et al.*, 2007), and the Southern Ocean (CHAT 16K, *Noble et al.*, 2013; SO213-84-1, *Ronge et al.*, 2015; E11-2, *Robinson et al.*, 2014) considered in this study. White arrows denote major circulation pattern of intermediate water masses in the North Pacific and Southern Ocean: Magenta and green spots indicate formation regions of AAIW and NPIW, shaded magenta and green areas mark modern lateral extent of intermediate waters in the Pacific Ocean. b: Latitudinal profile of present-day silicic acid concentrations from the North Pacific to the Southern Ocean [*Garcia et al.*, 2010] and major modern mid-depth to deep-water masses (white arrows): AAIW = Antarctic Intermediate Water; CDW = Circumpolar Deep Water; EUC = Equatorial Undercurrent; EqPIW = Equatorial Pacific Intermediate Water; NPIW = North Pacific Intermediate Water; PDW = Pacific Deep Water [modified after *Bostock et al.*, 2010]. This figure was generated with Ocean Data View [*Schlitzer*, 2015].

Pacific Deep Water (PDW) with only a very minor contribution of NPIW today (Figure 4.1) [Bostock *et al.*, 2010]. As the intermediate water masses flow towards the east, they supply nutrients via diapycnal mixing to the overlying waters masses. As a consequence of the high southern-sourced contribution today, carbon fixation by siliceous phytoplankton is limited by low silicic acid and iron availability in the Eastern Equatorial Pacific (EEP) making this region a significant net source of CO₂ to the atmosphere [Dugdale *et al.*, 2002].

Information regarding past ocean circulation changes can be reconstructed from the stable carbon isotopic composition ($\delta^{13}\text{C}$) measured on benthic foraminiferal tests. During the past thirty years, this proxy has been successfully used to investigate glacial to interglacial changes in water mass geometry and ocean circulation [e.g. Duplessy *et al.*, 1984; Curry *et al.*, 1988; Mix *et al.*, 1991; Curry *et al.*, 2005; Bostock *et al.*, 2010; Knudson and Ravelo, 2015a]. In the modern ocean, high(low) values of $\delta^{13}\text{C}$ of the Dissolved Inorganic Carbon (DIC) are indicative of low(high) nutrient concentrations and large-scale oceanic water mass circulation patterns [Kroopnick, 1985]. For $\delta^{13}\text{C}$ reconstructions of intermediate- and deep-water mass circulation changes the initial $\delta^{13}\text{C}$, where water masses are subducted into the ocean interior, has to be taken into account. The initial $\delta^{13}\text{C}$ value of a water mass is affected by air-sea gas exchange at the surface-ocean, which in turn is temperature-dependent. After isolation from the surface-ocean, the $\delta^{13}\text{C}$ of a given water mass is mainly altered by in-situ addition of CO₂ through respiration of sinking organic material. Today, a $\delta^{13}\text{C}_{\text{DIC}}$ of about 1 ‰ characterize surface waters of the North Atlantic where North Atlantic Deep Water (NADW) is formed. As it flows to the circum-Antarctic Ocean interior the continuous degradation of sinking organic particles reduces the original $\delta^{13}\text{C}_{\text{DIC}}$ of NADW to about 0.5 ‰. In the Southern Ocean deep-water further recirculates to the Indian and Pacific Ocean and lowest values of ~ -0.6 ‰ $\delta^{13}\text{C}_{\text{DIC}}$ are observed today in the deep subarctic Pacific. Since $\delta^{13}\text{C}$ of epibenthic foraminifera is closely related to the $\delta^{13}\text{C}_{\text{DIC}}$ of ambient seawater, past differences in nutrient content and water mass circulation patterns can be reconstructed from benthic foraminiferal tests preserved in marine sediments [e.g. Duplessy *et al.*, 1984].

Combined evidence of $\Delta^{14}\text{C}$ deep-water ventilation ages and benthic foraminiferal $\delta^{13}\text{C}$ records suggest changes in mid-depth circulation (the upper 1000 to ~ 2000 m water depth) of the North Pacific Ocean under glacial conditions [Duplessy *et al.*, 1988; Herguera *et al.*, 1992; Keigwin, 1998; Matsumoto *et al.*, 2002a; Okazaki *et al.*, 2012]. Accordingly, the mid-depth circulation of the North Pacific was strengthened by formation of Glacial North Pacific Intermediate Water (GNPIW). In contrast to today, it has been proposed that the Bering Sea formed intermediate waters during glacial times and played an important role in formation of GNPIW [e.g. Tanaka and Takahashi, 2005; Horikawa *et al.*, 2010]. Evidence for additional cold and well-oxygenated intermediate water in the glacial Bering Sea has been provided from a study based on changes in radiolarian assemblages [Tanaka and Takahashi, 2005]. Based on a neodymium isotope record (ϵ_{Nd}) it has been argued that Bering Sea intermediate water was a principal component of GNPIW during the glacial period [Horikawa *et al.*, 2010]. The formation of

glacial Bering Sea intermediate waters was explained by changes in high-latitude hydrological processes such as enhanced brine rejection and the resulting salinity increase favouring the subduction of cold surface waters to the mid-depth in the Bering Sea as important precursor of GNPIW [Rella *et al.*, 2012]. A recent study based on endobenthic foraminiferal stable oxygen ($\delta^{18}\text{O}$) and $\delta^{13}\text{C}$ records from the Bering Sea indicates that enhanced GNPIW formation was not only restricted to the Last Glacial Maximum (LGM), but also recurred during extreme glacial intervals of the last 1.2 Myr [Knudson and Ravelo, 2015a].

In the Southern Hemisphere there is so far no consensus about the amount of AAIW production during glacial boundary conditions. Based on $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ analyses on benthic foraminifera from the Australian margin it has been suggested that a colder and fresher water mass ventilated at intermediate depth, which was linked to a shift in the frontal zonation within the Southern Ocean [Lynch-Stieglitz *et al.*, 1994]. Furthermore, a study based on authigenic minerals from the Chilean margin found higher oxygen concentrations during glacial times, which were linked to an enhanced production of AAIW [Muratli *et al.*, 2010]. On the contrary, it has been proposed that stronger water column stratification in the Southern Ocean led to a reduced production of AAIW under glacial conditions [Pahnke and Zahn, 2005]. Accordingly, periods of increased intermediate water formation were linked to Southern Hemisphere warm episodes through a tight coupling between climate warming and intermediate water production at the high southern latitudes. A recent study combined benthic $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ records off New Zealand with modelling results and reconstructed the vertical extent of AAIW over the last 350 kyr [Ronge *et al.*, 2015]. These results showed that the vertical extent of AAIW changed on glacial-interglacial timescales with a significantly shallower AAIW subduction under glacial conditions. The shallower subduction of glacial AAIW has been related to an advanced winter sea-ice edge as well as enhanced freshwater flux from sea-ice melting that induced a salinity anomaly and resulted in formation of less dense intermediate waters in the Southern Ocean.

Studies based on ϵ_{Nd} records as well as $\Delta^{14}\text{C}$ shallow- and deep-water ventilation ages from the equatorial Pacific suggest a dominant role of the Southern Ocean in transferring climatic signals from the high latitudes towards the tropical regions during late Marine Isotope Stage (MIS) 2 [Pena *et al.*, 2013; de la Fuente *et al.*, 2015]. Accordingly, available reconstructions of changes in water mass signatures of the equatorial Pacific suggest a principal southern-source for tropical Pacific intermediate water masses during glacial times similar to today. In a recent study, Carriquiry *et al.* [2015] analysed $\delta^{13}\text{C}$ records at the western Baja California Margin and relates changes in mid-depth nutrient distribution to a larger influence of glacial AAIW to the tropical North Pacific. In contrast, Leduc *et al.* [2010] explained anomalies in glacial $\delta^{13}\text{C}$ of intermediate waters in the Eastern Tropical North Pacific (ETNP) by a switch from southern nutrient-poor to northern nutrient-enriched intermediate water masses due to a sustained formation of GNPIW. This notion is supported by a very recent ϵ_{Nd} data compilation from 55 core sites around the Pacific [Hu *et al.*, 2016] that revealed a significant offset in EEP ϵ_{Nd} signature values between LGM and Holocene values (by 1 – 2 epsilon units lower than during the

Holocene), which can only be explained by a higher contribution from northern-sourced waters [Hu *et al.*, 2016]. The enhanced penetration of northern-sourced water masses is in agreement with evidence for enhanced glacial mid-depth circulation reconstructed from $\delta^{13}\text{C}$ records of California margin sediment cores, however these records also point to spatial and temporal complexity in the ventilation history of the Northeast Pacific [Stott *et al.*, 2000]. Together, these results point to a more prominent role of GNPIW in shaping the mid-depth water mass characteristics of the glacial North Pacific. On the other hand, it still remains illusive how strengthened GNPIW circulation shaped the mid-depth water mass characteristics of the glacial North Pacific and whether GNPIW might have influenced the nutrient distribution, biological productivity and export patterns far beyond the northern high latitudes.

In this study, we report on stable isotope measurements derived from sedimentary records of the western subarctic Pacific (Bering Sea) and EEP to investigate spatiotemporal changes in GNPIW circulation and its influence on low-latitude Pacific water mass characteristics during the past 60 kyr. We chose a sediment core from the western Bering Sea located on Shirshov Ridge (SO201-2-101KL; 58°52.52'N, 170°41.45'E, 630 m water depth, Figure 4.1) and measured the $\delta^{13}\text{C}$ composition of the epibenthic foraminifera *Cibicides lobatulus* (*C. lobatulus*) as an indicator for past ventilation changes close to the source-region of GNPIW [Max *et al.*, 2014]. Today the western Bering Sea is poorly ventilated due to the absence of local intermediate water formation and water masses bathing core site SO201-2-101KL are dominated by upwelling of nutrient-rich PDW (Figure 4.1b). Additional $\delta^{13}\text{C}$ data of deep-dwelling planktonic foraminifera *Globorotaloides hexagonus* (*G. hexagonus*) from Ocean Drilling Program (ODP) Site 1240 (00°01.31'N, 82°27.76'W, 2921 m water depth, Figure 4.1) provide information about glacial changes of sub-thermocline water mass characteristics in the EEP. Modern water mass signatures of sub-thermocline waters at ODP Site 1240 are linked to the lower branch of the EUC, which brings nutrients to the surface ocean of the EEP (Figure 4.1b). By comparing water mass signatures of intermediate- to deep-water masses of the Pacific Ocean and Southern Ocean with sub-thermocline to mid-depth water masses in the tropical Pacific we examine whether (1) the influence of northern-sourced versus southern-sourced water masses on tropical Pacific intermediate- and sub-thermocline water masses of the EEP changed during the last glacial period and (2) discuss potential implications for sub-thermocline nutrient availability and biological productivity in the equatorial Pacific in the past.

4.2 Materials and Methods

4.2.1 Stable carbon ($\delta^{13}\text{C}$) and oxygen ($\delta^{18}\text{O}$) isotope measurements from benthic and deep-dwelling planktonic foraminifera

We measured the $\delta^{13}\text{C}$ and $\delta^{18}\text{O}$ isotope composition of epibenthic foraminifera *C. lobatulus* selected from sediment samples of western Bering Sea sediment core SO201-2-101KL and

deep-dwelling planktonic foraminifera *G. hexagonus* from samples of ODP Site 1240 in the Panama Basin (Figure 4.1; Supplementary Table S4.4.1 and S4.4.2). Sedimentation rates of 11 – 16 cm kyr⁻¹ have been reported for core SO201-2-101KL from Shirshov Ridge [Riethdorf *et al.*, 2013] and 6.4 – 25.2 cm kyr⁻¹ for ODP Site 1240 [Pena *et al.*, 2008]. According to our sampling scheme we achieved a millennial to centennial-scale resolution of proxy-data in this study with an average temporal resolution of ~0.25 kyr for core SO201-2-101KL and ~0.23 kyr for the last 60 kyr of ODP Site 1240, respectively. Stable isotope analyses in core SO201-2-101KL were made on samples of two to three specimens of *C. lobatulus* picked from the 250 – 400 µm size fractions. The stable isotopic composition of *G. hexagonus* of ODP Site 1240 were determined using five specimens per sample picked from the 250 – 315 µm size fraction.

It has been proposed that *C. lobatulus* preferentially lives attached to hard substrate on or slightly above the sediment surface and studies on living specimen indicated that this species faithfully records the $\delta^{13}\text{C}_{\text{DIC}}$ of ambient seawater [Schweizer *et al.*, 2009]. Some investigators have observed a positive offset in the $\delta^{13}\text{C}$ of *C. lobatulus* with regard to ambient bottom water $\delta^{13}\text{C}_{\text{DIC}}$ in some high-latitude settings of the North Atlantic Ocean [Mackensen *et al.*, 2000]. However, this effect was caused by high seasonal variability of the original ambient $\delta^{13}\text{C}_{\text{DIC}}$ -signal, confirmed by time-series measurements of water column $\delta^{13}\text{C}_{\text{DIC}}$ and related to the calcification of *C. lobatulus* during time intervals of maximum ventilation [Mackensen *et al.*, 2000]. We thus regard the $\delta^{13}\text{C}$ -signal *C. lobatulus* to reliably reflect $\delta^{13}\text{C}$ of ambient seawater.

Isotopic compositions of *C. lobatulus* and *G. hexagonus* were measured at the Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research, Germany, using a Thermo Fisher MAT 253 mass spectrometer coupled to a Kiel IV automatic carbonate preparation device. All stable isotope measurements were calibrated via the NBS-19 international standard and results are reported in δ -notation versus VPDB scale. Overall long-term analytical reproducibility of measurements based on internal laboratory standard (Solnhofen limestone) together with samples over a one-year period is better than ± 0.06 ‰ for $\delta^{13}\text{C}$ and ± 0.08 ‰ for $\delta^{18}\text{O}$.

4.2.2 Stable oxygen isotope composition ($\delta^{18}\text{O}$) and apparent calcification depth of deep-dwelling planktonic foraminifera *G. hexagonus*

Information regarding apparent calcification depth (ACD) of the planktonic foraminifera *G. hexagonus* is still sparse. We make a first attempt to determine the ACD at ODP Site 1240 to validate the depth habitat of *G. hexagonus* in the EEP. The ACD-estimation was done by comparing measured foraminiferal $\delta^{18}\text{O}_{\text{calcite}}$ from a near core-top sample (at 10 cm) to a theoretically expected equilibrium $\delta^{18}\text{O}$ values of calcite ($\delta^{18}\text{O}_{\text{equilibrium}}$) that foraminifera would incorporate in dependence of modern water temperature, salinity and $\delta^{18}\text{O}$ values of seawater ($\delta^{18}\text{O}_{\text{seawater}}$). In order to calculate $\delta^{18}\text{O}_{\text{seawater}}$, the $\delta^{18}\text{O}_{\text{seawater}}$ -salinity relationships given by Leduc *et al.* [2007] for 0 – 40 m water depth:

$$\delta^{18}\text{O}_{\text{seawater}} (\text{‰}) = 0.253 \cdot S - 8.52,$$

and for >40 m water depth:

$$\delta^{18}\text{O}_{\text{seawater}} (\text{‰}) = 0.471 \cdot S - 16.15$$

were used in conjunction with annual salinity data derived from World Ocean Atlas 2009 [Antonov *et al.*, 2010].

Several established $\delta^{18}\text{O}$ -paleotemperature equations [Epstein *et al.*, 1953; Shackleton, 1974; Kim and O'Neil, 1997; Bemis *et al.*, 1998] were considered for $\delta^{18}\text{O}_{\text{calcite}}$ as absolute ACD estimation strongly depends on the applied temperature equation [Wejnert *et al.*, 2013] (Figure 4.2). Modern temperatures are derived from the World Ocean Atlas 2009 [Locarnini *et al.*, 2010], and $\delta^{18}\text{O}_{\text{seawater}}$ were included after correcting $\delta^{18}\text{O}_{\text{seawater}}$ to the VPDB scale by subtracting the $\delta^{18}\text{O}_{\text{seawater}}$ -conversion factor given in Bemis *et al.* [1998]. The water depth showing the best match between $\delta^{18}\text{O}_{\text{calcite}}$ and $\delta^{18}\text{O}_{\text{equilibrium}}$ is taken as the ACD of *G. hexagonus* (Figure 4.2).

Figure 4.2. Apparent Calcification Depth (ACD) of planktonic foraminifera *G. hexagonus* in the Eastern Equatorial Pacific. ACD of *G. hexagonus* at ODP Site 1240 was inferred from best match between measured foraminiferal $\delta^{18}\text{O}_{\text{calcite}}$ values and corresponding calculated theoretically present $\delta^{18}\text{O}_{\text{equilibrium}}$ value, which were determined using various paleotemperature equations (black partly dashed lines), modern water temperatures [Locarnini *et al.*, 2010] and $\delta^{18}\text{O}_{\text{seawater}}$ (gray line). The blue bar indicates the ACD range of *G. hexagonus* considering all used equations.

The calculated ACD suggests that *G. hexagonus* dwells below the thermocline in 340 – 430 m water depth similar to estimated depth habitats defined by Ortiz *et al.* [1996] in the North Pacific.

Further support comes from a very recent ACD assessment from the western equatorial Pacific, which concludes that deep-dwelling *G. hexagonus* is a suitable proxy for tracing properties of equatorial sub-thermocline water masses [Rippert *et al.*, 2016, *this thesis*]. Hence, the stable isotopic composition of *G. hexagonus* is considered to reflect the water mass properties of sub-thermocline waters of the EEP.

4.2.3 Stratigraphic approach and age models

The stratigraphic framework of western Bering Sea core SO201-2-101KL was constructed using a multi-proxy approach described in detail in Riethdorf *et al.* [2013]. Briefly, information derived from high-resolution X-ray fluorescence (XRF) and spectrophotometric logging data (color b^*) of core SO201-2-101KL were used for correlation to millennial-scale variability preserved in the NGRIP ice core [Andersen *et al.*, 2004] according to the GICC05 timescale [Svensson *et al.*, 2008] (Figure 4.3a). The tuning of core SO201-2-101KL to NGRIP was further validated by five planktonic radiocarbon ages spanning the time interval from the onset of MIS 2 to the time interval of the last glacial termination (Figure 4.3a) [see Max *et al.*, 2012].

We adopted the established age scale of ODP Site 1240 described in the work of Pena *et al.* [2008]. The stratigraphic framework of ODP Site 1240 was constructed from 17 AMS ^{14}C ages based on monospecific samples of the planktonic foraminifera *Neogloboquadrina dutertrei* (*N. dutertrei*) and tuning of the initiation of *N. dutertrei* $\delta^{13}\text{C}$ minima at ODP Site 1240 to the CO_2 increase in the Vostok CO_2 , as shown by Spero and Lea [2002]. Graphical correlation of planktonic foraminiferal Mg/Ca derived sea surface temperatures (SST) from ODP Site 1240 to Antarctic Vostok deuterium records was used to get additional age controls for deeper parts of the core [see supplement of Pena *et al.*, 2008 for more details] (Figure 4.3b).

4.3 Results

Under modern conditions, the western Bering Sea is poorly ventilated due to the absence of local intermediate water formation. Today, water masses bathing core site SO201-2-101KL are dominated by upwelling of nutrient-rich PDW with very low $\delta^{13}\text{C}$ signatures of $\sim -0.6\text{‰}$ (Figures 4.1 and 4.4). The nutrient-rich and ^{13}C -depleted signature of PDW results from its long isolation from the sea surface and continuous respiration of organic matter along its path from the Southern Ocean into the North Pacific [Herguera *et al.*, 2010]. The reconstructed glacial (60 – 20 ka) $\delta^{13}\text{C}$ values show a pronounced variability on millennial timescales, in particular during MIS 3, and vary between -0.8‰ – 0.2‰ (Figure 4.4). Upon millennial-scale variability a long-term trend towards increased $\delta^{13}\text{C}$ of Bering Sea intermediate water since the beginning of MIS 3 is clearly visible in core SO201-2-101KL, which culminated during early MIS 2 (~ 29 ka) with $\delta^{13}\text{C}$ signatures of up to $\sim 0.3\text{‰}$ (Figure 4.4). During MIS 2 $\delta^{13}\text{C}$ values show a long-term decrease with $\delta^{13}\text{C}$ signatures reaching $\sim -0.2\text{‰}$ at the beginning of the last deglaciation (~ 17 ka).

Figure 4.3. a: Comparison of high-resolution XRF core-logging data (Ca/Ti-ratio) from core SO201-2-101KL to NGRIP ice-core record. Numbers indicate Dansgaard-Oeschger Interstadials in NGRIP [Andersen *et al.*, 2004] and SO201-2-101KL [this study] during the past 60 kyr [Riethdorf *et al.*, 2013]. b: The stratigraphic framework of ODP Site 1240 based on 17 AMS ^{14}C ages and graphical tuning deeper parts of the cores to the Vostok ice core record [Petit *et al.*, 1999; Pena *et al.*, 2008]. Available AMS- ^{14}C dating's derived from core SO201-2-101KL and ODP Site 1240 are given by blue and purple squares at the bottom.

The deep-dwelling planktonic foraminifera *G. hexagonus* record from ODP Site 1240 serves as proxy for changes in $\delta^{13}\text{C}$ signatures of sub-thermocline water masses upwelled in the EEP (Figure 4.4). Under modern conditions, water mass upwelling to the surface of the EEP happens via the lower branch of the EUC with modern $\delta^{13}\text{C}$ signatures of ~ 0.1 ‰ (Figures 4.1 and 4.4). During MIS 3 ($\sim 60 - 30$ ka) the *G. hexagonus* $\delta^{13}\text{C}$ proxy record indicates the presence of relatively ^{13}C -enriched (nutrient-depleted) water masses with $\delta^{13}\text{C}$ signatures of $0.1 - 0.2$ ‰ and relatively low variability in $\delta^{13}\text{C}$ of sub-thermocline waters (Figure 4.4). A first switch to relatively ^{13}C -depleted sub-thermocline water masses in the EEP is apparent during early MIS 2, and most ^{13}C -depleted values of ~ -0.4 ‰ are found at the beginning of the last deglaciation (~ 17 ka).

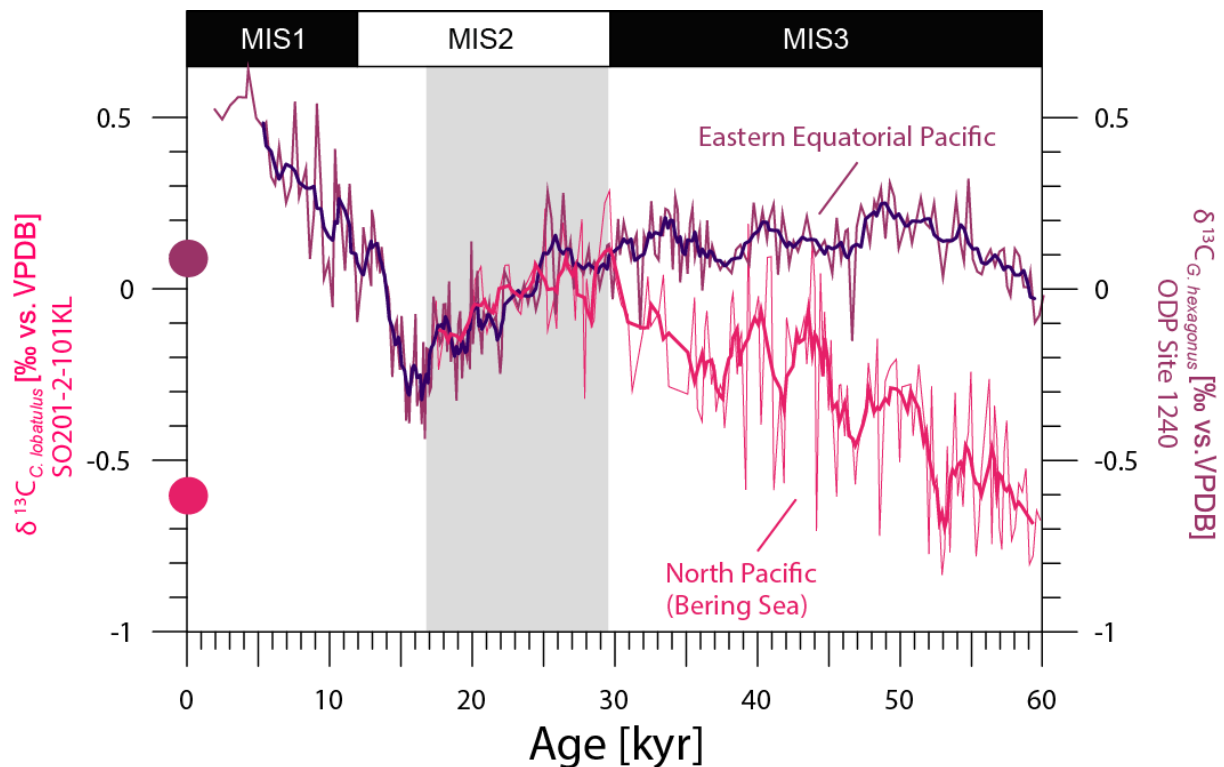

Figure 4.4. Detailed comparison of mid-depth benthic $\delta^{13}\text{C}$ record from sediment core SO201-2-101KL from the subarctic Pacific (Bering Sea) with $\delta^{13}\text{C}$ record of deep-dwelling (sub-thermocline) planktonic foraminifera *G. hexagonus* derived from ODP Site 1240 in the Eastern Equatorial Pacific during the past 60 kyr. Grey shaded area marks times of convergence between the given $\delta^{13}\text{C}$ records during MIS 2. Coloured circles indicate $\delta^{13}\text{C}_{\text{DIC}}$ composition of water masses bathing the respective core sites under modern conditions [Key *et al.*, 2004].

4.4 Discussion

Based on proxy data of marine productivity and benthic foraminiferal stable isotope records a recent study suggested that the long-term increase in $\delta^{13}\text{C}$ Bering Sea intermediate water was related to local formation of waters masses with lower salinity and higher oxygen content under glacial conditions [Schlung *et al.*, 2013]. Rella *et al.* [2012] argued that an eastward displacement of the Aleutian Low and a shift to predominantly northerly winds over the Bering Sea created favourable conditions for active polynya formation and brine rejection coupled to sea-ice formation, which led to intermediate water production as one potential source-region of GNPIW during the glacial period. However, changes in thermodynamic (temperature-dependent) equilibration between the surface ocean $\delta^{13}\text{C}_{\text{DIC}}$ and the atmospheric CO_2 also influence isotopic fractionation, whereby surface ocean $\delta^{13}\text{C}_{\text{DIC}}$ increases by 0.1 ‰ with each 1°C decrease in surface ocean temperature [Mook *et al.*, 1974]. Given that glacial production of intermediate waters in the western Bering Sea was supposedly linked to sea-ice formation during winter, when surface ocean temperature were always close to the freezing point, temperature-dependent changes in air-sea gas exchange of western Bering Sea surface waters should have had a minor effect on the $\delta^{13}\text{C}_{\text{DIC}}$ signal. A recent study showed that during stadial periods of the deglaciation most of the western Bering Sea was covered by seasonal sea ice [Méheust *et al.*, 2016], thus providing favourable conditions for intermediate water formation. Moreover, benthic $\delta^{13}\text{C}$ data from proximal core SO201-2-85KL point to a decline in $\delta^{13}\text{C}$ and reduced ventilation during deglacial warm stages and the early Holocene when sea-ice cover was substantially reduced [Max *et al.*, 2012; Max *et al.*, 2014].

4.4.1 Glacial contribution of northern- versus southern-sourced water masses in the Eastern Tropical North Pacific (~8°N)

In a first step, we compare the benthic $\delta^{13}\text{C}$ of mid-depth records from the Southern Ocean (SO213-84-1; Ronge *et al.*, 2015), the subarctic Pacific (SO201-2-101KL; *this study*) and a deep-water benthic $\delta^{13}\text{C}$ record from the Northeast Pacific (W8709A-13PC; Lund and Mix, 1998) with mid-depth $\delta^{13}\text{C}$ signatures derived from sediment core MD02-2529 [Leduc *et al.*, 2010] located in the ETNP to assess the influence of northern- versus southern-sourced water masses on EqPIW characteristics during the past 60 kyr (Figures 4.1 and 4.5a). The core site of MD02-2529 in the ETNP is situated at the modern confluence of northern oxygen-poor and southern oxygen-rich waters, and thus is ideally located to investigate past changes in the respective latitudinal extents of northern versus southern-sourced water masses in the past [Leduc *et al.*, 2010].

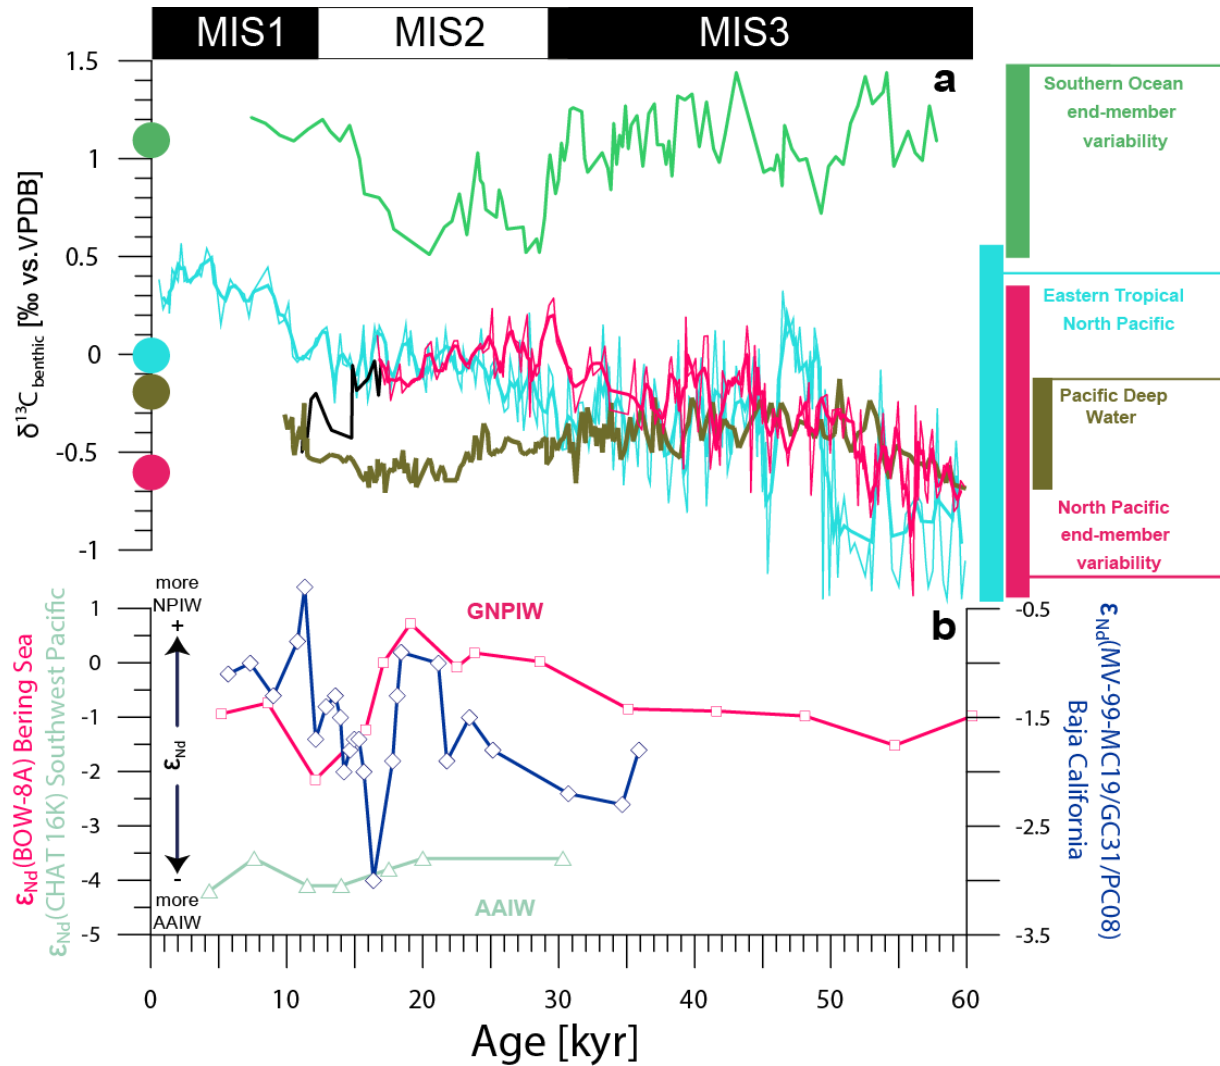

Figure 4.5 Benthic $\delta^{13}\text{C}$ records and ϵ_{Nd} signatures from intermediate waters of the North Pacific (GNPIW), off Baja California, the Eastern Tropical North Pacific (EqPIW) and the Southern Ocean (AAIW) compared to benthic $\delta^{13}\text{C}$ deep-water (PDW) variability for the last 60 kyr. a: Benthic $\delta^{13}\text{C}$ record from Southern Ocean core SO213-84-1 (AAIW, in green) [Ronge *et al.*, 2015], benthic $\delta^{13}\text{C}$ record from MD02-2529 located in the Eastern Tropical North Pacific (in light blue) [Leduc *et al.*, 2010], benthic intermediate-water $\delta^{13}\text{C}$ record from Bering Sea core SO201-2-101KL (in magenta) [this study] and SO201-2-85KL (in black) [Max *et al.*, 2014], deep-water benthic $\delta^{13}\text{C}$ record from core W8709A-13PC (in brown) [Lund and Mix, 1998]. b: End-member intermediate-water mass ϵ_{Nd} records from southern Bering Sea core BOW-8A (GNPIW, in magenta) [Horikawa *et al.*, 2010] and southwest Pacific core CHAT 16K (AAIW, in light green) [Noble *et al.*, 2013] together with ϵ_{Nd} signatures derived from sediment cores off Baja California (in blue) [Basak *et al.*, 2010]. Coloured vertical bars indicate total variability in measured $\delta^{13}\text{C}$ at respective core sites. Coloured circles indicate $\delta^{13}\text{C}_{\text{DIC}}$ composition of water masses bathing respective core sites under modern conditions [Key *et al.*, 2004].

The glacial $\delta^{13}\text{C}$ end-member variability of AAIW is reflected by sediment core SO213-84-1 off New Zealand [Ronge *et al.*, 2015] (Figure 4.5a). There, glacial $\delta^{13}\text{C}$ signatures of AAIW range between $\sim -0.5 - 1.4$ ‰ and characterizing southern-sourced intermediate water masses. The

long-term evolution of $\delta^{13}\text{C}$ -signatures between AAIW and intermediate waters in the North Pacific and ETNP reveals remarkable differences in temporal variability under glacial conditions (Figure 4.5a). Moreover, huge gradients in $\delta^{13}\text{C}$ (up to 2 ‰) between Southern Ocean core SO213-84-1 and MD02-2529 from the ETNP [Leduc *et al.*, 2010] clearly separate ^{13}C -enriched (more nutrient-depleted) signatures of AAIW from ^{13}C -depleted (more nutrient-enriched) signatures of EqPIW under glacial conditions (Figure 4.5a). Evidence for a weakened production or shoaling of glacial AAIW has been inferred from $\delta^{13}\text{C}$ -records off New Zealand [Pahnke and Zahn, 2005; Ronge *et al.*, 2015], which generally points to a glacial change in relative contribution of intermediate waters from the Southern Ocean to the tropical Pacific. However, large gradients and the discrepancy in temporal evolution of $\delta^{13}\text{C}$ signatures of EqPIW and AAIW cannot be explained by $\delta^{13}\text{C}$ variability of southern-sourced intermediate waters alone and point to additional water masses influencing the glacial mid-depth tropical Pacific.

Next, we compare our new benthic $\delta^{13}\text{C}$ record from the mid-depth subarctic Pacific (SO201-2-101KL) and the benthic $\delta^{13}\text{C}$ record of PDW from the Northeast Pacific (W8709A-13PC) [Lund and Mix, 1998] with EqPIW $\delta^{13}\text{C}$ water mass characteristics (MD02-2529) [Leduc *et al.*, 2010] during the past 60 kyr (Figures 4.1 and 4.5a). Millennial-scale variability superimposed on the long-term $\delta^{13}\text{C}$ trend of EqPIW is more pronounced compared to the $\delta^{13}\text{C}$ -signal recorded in SO201-2-101KL (GNPIW) or W8709A-13PC (PDW) during early MIS 3 (55 – 45 ka). In addition EqPIW $\delta^{13}\text{C}$ values oscillate between $\delta^{13}\text{C}$ signatures of GNPIW and PDW during MIS 3 (60 – 30 ka). During this time, there is no clear relationship to northern- or southern-sourced intermediate waters, and rather admixing of different source water masses to EqPIW is likely. On the other hand, clear similarities in the long-term evolution in $\delta^{13}\text{C}$ between the intermediate water records derived from subarctic Pacific core SO201-2-101KL and sediment core MD02-2529 from the ETNP are observed since at least ~29 ka (Figure 4.5a). Moreover, glacial gradients in $\delta^{13}\text{C}$ between GNPIW and EqPIW are relatively small and vary between 0.2 – 0.5 ‰. In contrast, absolute $\delta^{13}\text{C}$ signatures as well as the temporal evolution of EqPIW and PDW differs substantially such as $\delta^{13}\text{C}$ of EqPIW increases steadily, whereas $\delta^{13}\text{C}$ of PDW shows a long-term trend to more depleted ^{13}C signatures during MIS 2 (Figure 4.5a). Accordingly, available deep-water ventilation ages as well as the long-term trend in deep-water $\delta^{13}\text{C}$ of the North Pacific indicate that glacial PDW was similar or even less well ventilated than today [Lund and Mix, 1998; Galbraith *et al.*, 2007; Lund *et al.*, 2011] and the ventilation history different to the mid-depth circulation dynamics of the North Pacific [Kennett and Ingram, 1995; Stott *et al.*, 2009]. Altogether, our results indicate that intermediate waters in the subarctic Pacific and ETNP (GNPIW and EqPIW) share similar glacial $\delta^{13}\text{C}$ signatures, which are indicative for the presence of nutrient-enriched intermediate water masses, but are apparently different to $\delta^{13}\text{C}$ signatures of AAIW or PDW (Figure 4.5a). Given that GNPIW features slightly higher $\delta^{13}\text{C}$ signatures compared to EqPIW masses our results point to the advection of northern-sourced intermediate water masses towards the tropical Pacific. Thus, from similarities in long-term evolution of $\delta^{13}\text{C}$ between the North Pacific and ETNP intermediate water records we argue that relatively nutrient-

enriched GNPIW generally extended further south to the tropical Pacific under glacial conditions. During the last deglaciation (~17 – 15 ka), however, intermediate water $\delta^{13}\text{C}$ -signals at the ETNP and North Pacific starts to diverge substantially. The $\delta^{13}\text{C}$ signatures in the ETNP increase, while the $\delta^{13}\text{C}$ values decrease at site SO201-2-85KL in the subarctic Pacific (Figure 4.5a).

Independent evidence for enhanced glacial influence of northern-sourced intermediate waters to the low-latitude Pacific comes from the comparison of available ϵ_{Nd} records of the Bering Sea and off Baja California [Basak *et al.*, 2010; Horikawa *et al.*, 2010] (Figure 4.5b). In particular, ϵ_{Nd} data at the intermediate depth in the Bering Sea show radiogenic values explicitly indicating that Bering Sea surface water masses (marked by more radiogenic ϵ_{Nd} signatures) were subducted to intermediate depths under glacial conditions [Horikawa *et al.*, 2010]. At the same time, glacial ϵ_{Nd} values derived from a sediment record off Baja California point to the presence of more radiogenic intermediate water masses, which has been linked to admixture of dominantly northern-sourced intermediate waters [Basak *et al.*, 2010]. Furthermore, available information of glacial ϵ_{Nd} signatures from a sediment core in the southwest Pacific [Noble *et al.*, 2013] clearly distinguish less radiogenic ϵ_{Nd} signatures of AAIW from signals of more radiogenic intermediate water masses found in the Bering Sea or off Baja California (Figure 4.5b). Altogether, results from ϵ_{Nd} records are in line with enhanced glacial advection of northern-sourced intermediate water masses towards the tropical Pacific (Figures 4.1 and 4.5b). However, rapid changes in Bering Sea and Baja California ϵ_{Nd} signatures are visible during the last deglaciation that point to a switchback to reduced influence of northern-sourced intermediate water masses to the low-latitude Pacific since ~17 ka (Figure 4.5b).

The combined evidences from $\delta^{13}\text{C}$ and ϵ_{Nd} proxy data of the subarctic Pacific, the eastern North Pacific (Baja California), the ETNP and Southern Ocean suggest that northern-sourced intermediate waters extended further south to the ETNP under glacial conditions (Figures 4.5a and b). This is in agreement with a scenario proposed by Herguera *et al.* [2010], in which a deepening of the main thermocline and cooling of the high-latitude North Pacific would lead to a south-eastward expansion of GNPIW circulation and greater glacial influence of northern-sourced intermediate water on the tropical Pacific. Therefore, we propose that glacial changes in the relative contribution of intermediate waters from both the Southern Ocean and North Pacific are important in re-circulating excess nutrients from the high-latitude oceans towards the low latitude-regions of the Pacific Ocean. We suggest that the observed glacial changes in $\delta^{13}\text{C}$ -signatures of tropical intermediate waters in the ETNP are linked to additional contribution of northern-sourced intermediate waters. Increased glacial contribution from relatively nutrient-enriched, northern-sourced intermediate water (relative to AAIW) to the low-latitude Pacific is also in line with a regional pattern of elevated marine productivity observed along the tropical North Pacific [Arellano-Torres *et al.*, 2011]. Altogether, our results further confirm considerations of a southward expansion of GNPIW to explain the $\delta^{13}\text{C}$ signatures found in the mid-depth tropical Pacific during MIS 2 [Herguera *et al.*, 2010].

4.4.2 Evidence for increased GNPIW influence on the Eastern Equatorial Pacific since MIS 2?

To assess whether GNPIW expanded further south to the equatorial upwelling system, we compare the variability in $\delta^{13}\text{C}$ of GNPIW and AAIW with a new sub-thermocline $\delta^{13}\text{C}$ proxy record of the deep-dwelling planktonic foraminifera *G. hexagonus* from ODP Site 1240. Glacial variations in $\delta^{13}\text{C}$ of sub-thermocline water masses are interpreted as both changes in incoming nutrients and export productivity in the surface ocean of the EEP. During MIS 3 (~60 – 30 ka) the *G. hexagonus* $\delta^{13}\text{C}$ proxy record indicates the presence of relatively ^{13}C -enriched (nutrient-depleted) water masses with low variability in $\delta^{13}\text{C}$ of sub-thermocline waters of the EEP (Figure 4.6a). At the same time, GNPIW shows distinctly lower (more-nutrient-rich) $\delta^{13}\text{C}$ values with higher temporal variability than EEP sub-surface waters. However, apparent similarities are observed since ~29 ka at the beginning of MIS 2, where absolute $\delta^{13}\text{C}$ values as well as the long-term trend indicate more nutrient-enriched sub-thermocline water masses recorded in $\delta^{13}\text{C}$ of *G. hexagonus* at ODP Site 1240, which closely follows the temporal evolution of the $\delta^{13}\text{C}$ signature advected towards the tropical Pacific via GNPIW (Figure 4.6a).

Interestingly, another rapid switch to monotonically increasing $\delta^{13}\text{C}$ of *G. hexagonus* is visible during the last deglaciation, which suggests a decoupling from northern-sourced intermediate waters between ~17 – 15 ka. The transition from ^{13}C -depleted (more nutrient-enriched) to rather ^{13}C -enriched (more nutrient-depleted) sub-surface water implies another significant change in characteristics of source water masses along with changes in biological productivity in the EEP during the last deglaciation (Figures 4.6a and b). Simultaneously, intermediate waters in the North Pacific became further ^{13}C -depleted and seems to be decoupled from sub-thermocline waters in the EEP. This is in line with a recent study on surface ocean productivity at ODP Site 1240, which showed that southern-sourced intermediate waters played a more dominant role for the nutrient redistribution in the EEP since the early deglaciation [e.g. *Calvo et al.*, 2011]. Dissimilar trends are also evident between northern-sourced intermediate water and mid-depth water masses in the ETNP, probably due to a reduced lateral extent of GNPIW during the last deglaciation (Figure 4.5a). Since then, mid-depth waters in the ETNP seems to follow the temporal variability of southern-sourced intermediate water that imply a larger influence of ^{13}C -enriched (more nutrient-depleted) AAIW in the tropical Pacific. However, we note that large gradients between $\delta^{13}\text{C}$ of sub-thermocline waters in the EEP and AAIW are also visible during the last deglaciation and Holocene. Still, available benthic $\delta^{13}\text{C}$ records from the mid-depth to deep North Pacific do not cover the whole Holocene and impede further interpretation of $\delta^{13}\text{C}$ variability in the ETNP during this time.

Past changes in sub-thermocline water mass signatures in the EEP have been usually linked to differences in advection and/or source-water mass characteristics of Southern Ocean water masses to the tropical Pacific. Rapid changes in meridional transport of southern-sourced intermediate water towards the tropical regions have been proposed from proposed from ϵ_{Nd}

records over the last 30 kyr [Pena et al., 2013]. A recent study investigating Southern Ocean and EEP shallow- and deep-water ventilation ages suggest that relatively old water masses (PDW/UCDW) upwelled to EEP thermocline waters and proposed a dominant deep southern-source during late MIS 2 [de la Fuente et al., 2015]. A study reconstructing radiocarbon activity of mid-depth waters from sediment cores off Baja California also pointed to the presence of slightly older intermediate waters in the eastern North Pacific during the latter part of the glacial period [Marchitto et al., 2007], which might also explain glacial age anomalies in the surface ocean of the EEP. Thus, we explain changes in $\delta^{13}\text{C}$ of sub-thermocline water masses of the EEP between MIS 3 and MIS 2 by changes in source water masses characteristics probably due to variable ocean interior transport pathways reaching the equatorial Pacific under glacial conditions. Based on the apparent similarities between $\delta^{13}\text{C}$ -signatures of northern-sourced intermediate waters, mid-depth waters in the Panama basin of the ETNP and sub-thermocline waters in the EEP (Figures 4.5a and 4.6a), we argue for additional intrusion of GNPIW into sub-thermocline water masses of the EEP during MIS 2.

4.4.3 “North Pacific Nutrient Leakage”

We provide the first evidence that relatively ^{13}C -depleted (nutrient-enriched) GNPIW influenced glacial EEP sub-thermocline waters during MIS 2 and discuss further potential implications on marine productivity of the equatorial Pacific regions at that time (Figures 4.6a - c). Nitrogen and silicon isotopes are often used as diagnostic tools for reconstructing past nutrient cycling. With higher nutrient consumption, both substrate (dissolved nutrients) and products generated from it become progressively enriched in heavier isotopes. Indeed several studies of sediment cores in the EEP found evidence for changes in marine productivity and nutrient utilization during MIS 2 [Kienast et al., 2007; Pichevin et al., 2009; Robinson et al., 2009; Dubois et al., 2011] (Figure 4.6b). Overall similarities between these records demonstrate that they are not primarily influenced by local processes at the deposition site, but rather reflect a robust signal of regional changes in nutrient delivery and biological productivity in the EEP [Dubois et al., 2011]. Pichevin et al. [2009] found that the glacial biological carbon pump in the EEP was more efficient due to a relaxation of nutrient limitation and speculated about its contribution to lower atmospheric CO_2 conditions during MIS 2.

Glacial relaxation of nutrient limitation and concurrent maxima in biological productivity in the EEP have been usually related to the redistribution of excess nutrients (mainly silicic acid) from the Southern Ocean via “ocean tunnelling” as proposed by the Silicic Acid Leakage Hypothesis [Matsumoto et al., 2002b]. At the same time, changes in the contribution of northern-sourced intermediate waters are often neglected e.g. by assuming that the relative contribution from northern- and southern-sourced water did not change significantly in the past [e.g. Dubois et al., 2011; Pena et al., 2013]. However, studies using diatom-bound silicon and nitrogen isotopes as proxies for nutrient utilization suggested enhanced glacial drawdown of silicic acid and nitrate

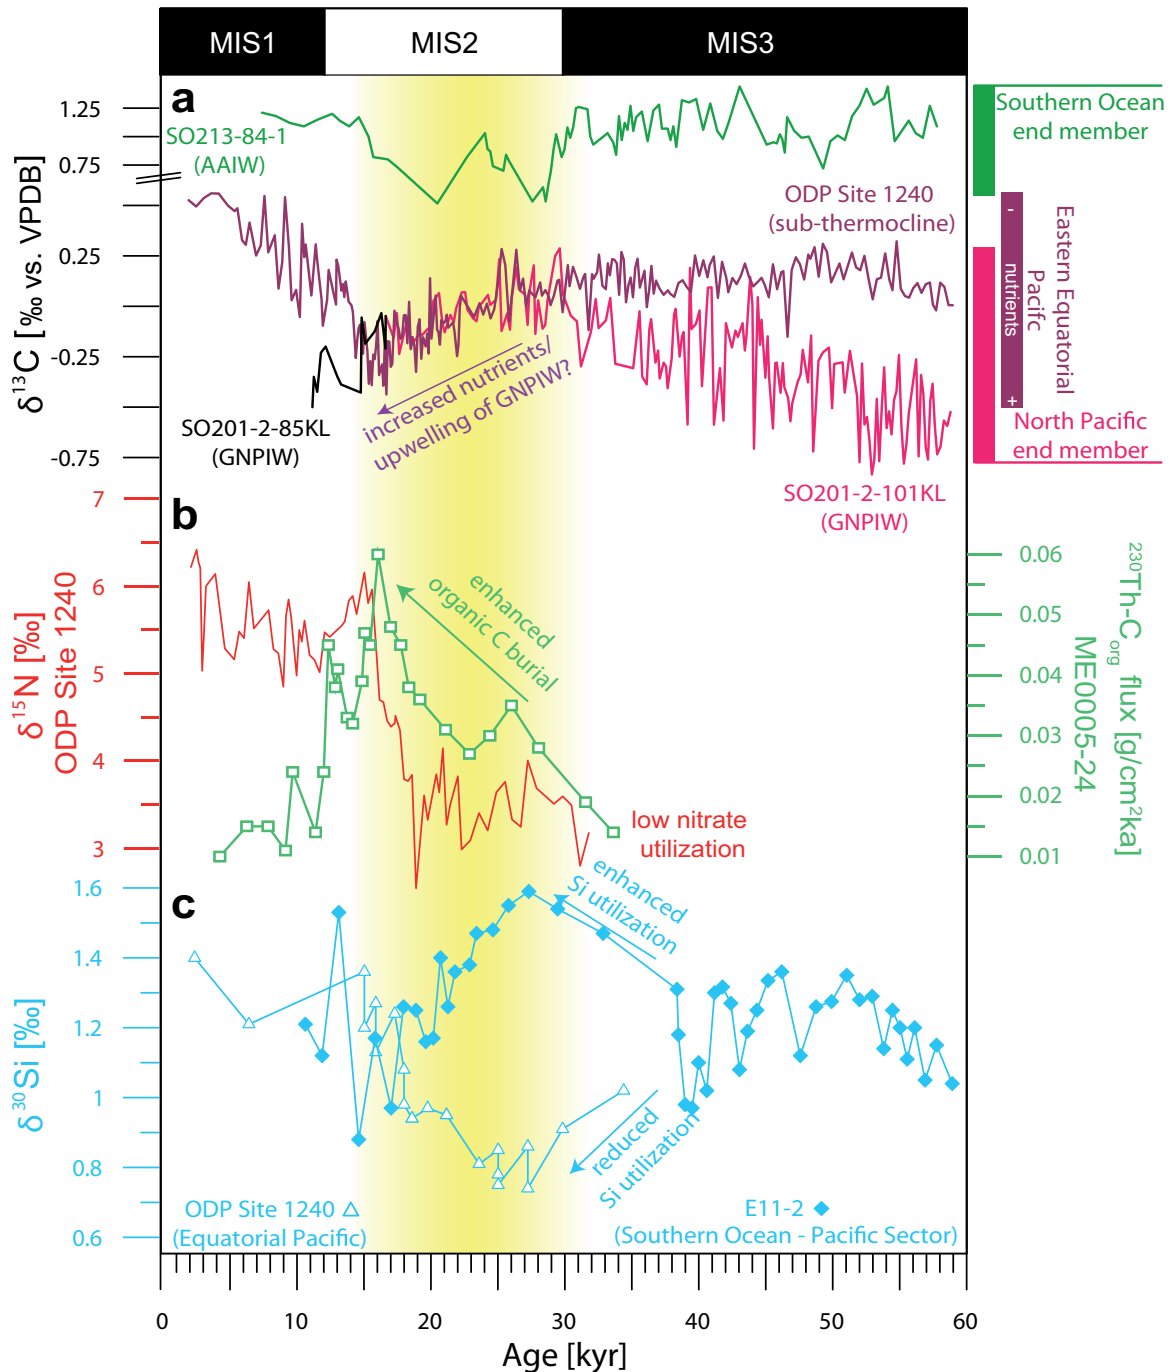

Figure 4.6. Reconstructed $\delta^{13}\text{C}$ variability of GNPIW versus AAIW compared to glacial changes in $\delta^{13}\text{C}$ of sub-thermocone waters, biological productivity and nutrient utilization in the Eastern Equatorial Pacific (EEP) and Southern Ocean. a: $\delta^{13}\text{C}$ record of GNPIW (SO201-2-85KL, *Max et al.*, 2014; SO201-2-101KL; *this study*) compared to $\delta^{13}\text{C}$ composition of AAIW (SO213-84-1, *Ronge et al.*, 2015) and deep-dwelling planktonic foraminifera $\delta^{13}\text{C}$ record of *G. hexagonus* (ODP Site 1240, *this study*) during the past 60 kyr. b: $\delta^{15}\text{N}$ record at ODP Site 1240 in the EEP [*Pichevin et al.*, 2009] together with ^{230}Th -normalized C_{org} flux of neighbouring core ME0005-24 [*Kienast et al.*, 2007]. c: $\delta^{30}\text{Si}_{\text{Diatom}}$ isotope composition of ODP Site 1240 in the EEP [*Pichevin et al.*, 2009] compared to $\delta^{30}\text{Si}_{\text{Diatom}}$ composition derived from core E11-2 [*Robinson et al.*, 2014] located in the Pacific Zone of the Southern Ocean. Yellow shaded bar marks times of increased GNPIW contribution to sub-thermocone waters of the EEP during MIS 2.

along with higher glacial opal fluxes in the Pacific Subantarctic Zone of the Southern Ocean during MIS 2 [Bradtmiller *et al.*, 2009; Robinson *et al.*, 2005, 2014]. These results show that, in contrast to the EEP, silicic acid and nitrate have been utilized more efficiently and became rather “trapped” north of the Antarctic Polar Front in the glacial deep Southern Ocean (Figures 4.6b and c). However, it has been also shown that average glacial opal fluxes were less than during the Holocene south of the Antarctic Polar Front [Bradtmiller *et al.*, 2009]. Whether the glacial Southern Ocean provides sufficient nutrients via “ocean tunnelling” to enhance marine productivity at the EEP as predicted by the Silicic Acid Leakage Hypothesis is still discussed controversial [Hendry and Brzezinski, 2014; Robinson *et al.*, 2014].

Interestingly, times of enhanced organic carbon flux rates and low nutrient utilization (silicic acid and nitrate) in the EEP are visible since the beginning of MIS 2 and generally coincided with the proposed changes in additional contributions of relatively nutrient-rich GNPIW to equatorial Pacific sub-thermocline water masses (Figures 4.6b and c). Invoking an additional export of unutilized (preformed) nutrients from the high-latitude North Pacific via nutrient-enriched GNPIW (here named as “North Pacific Nutrient Leakage”) thus might be another, yet unconsidered, process to explain relieved nutrient limitation and a stimulated biological pump in the EEP during MIS 2. Unfortunately, less is known about glacial changes in utilization of major nutrients, such as silicon or iron in the source region of GNPIW. Some studies propose low biological productivity and nutrient utilization (nitrate) in the Bering Sea due to a decrease in productivity, or an increase in nitrate availability through changes in vertical mixing under glacial conditions [Riethdorf *et al.*, 2013; Schlung *et al.*, 2013]. Other studies point to near-complete nutrient utilization (nitrate) in the Bering Sea and western subarctic Pacific during glacial times [Brunelle *et al.*, 2007, 2010]. A recent study emphasizes the role of strong physical stratification of the glacial subarctic Pacific surface waters, which prevented additional flux of nitrate from underlying water, such that available surface nitrate was used to near completion [Knudson and Ravelo, 2015b]. Our results propose that additional influence of nutrient-rich North Pacific mid-depth waters to the tropical Pacific via GNPIW might hold new clues about glacial productivity changes in the EEP, but need to be further evaluated in order to understand the role of enhanced influence of GNPIW to the low-latitude Pacific under glacial conditions.

During the deglaciation, the resumption of intense overturning within the Southern Ocean led to a higher injection of relatively nutrient-depleted southern-sourced water masses into the EqPIW. As a consequence, decreasing nutrient concentrations and increasing nutrient consumption are recorded in the EqPIW (Figure 4.6). However, we can only speculate about the offset in timing between the onset of EqPIW $\delta^{13}\text{C}$ changes (shown by *G. hexagonus*) and the increase in $\delta^{15}\text{N}$ in ODP Site 1240. The switch in relative end-member contribution during the deglaciation possibly causes variations in intermediate water suboxia and hence water column denitrification [Robinson *et al.*, 2009]. This would affect the nitrogen isotopes only as *G. hexagonus* seems to be more insensitive to varying oxygen concentrations [Rippert *et al.*,

2016, *this thesis*]. Nonetheless, the discrepancy in timing needs to be further investigated in combination with $\delta^{15}\text{N}$ studies from the high latitudes.

4.5 Conclusions

Here we report on new foraminiferal $\delta^{13}\text{C}$ records from the western subarctic Pacific (Bering Sea) and EEP spanning the past 60 kyr. Combined evidence of $\delta^{13}\text{C}$ from core SO201-2-101KL and ϵ_{Nd} records of the Bering Sea points to a long-term increase in GNPIW formation since the onset of MIS 3, which culminated early in MIS 2 (~29 ka). The comparison between benthic foraminiferal $\delta^{13}\text{C}$ records of SO201-2-101KL and marine sediment core MD02-2529 from the Panama Basin as well as ϵ_{Nd} records of the Bering Sea and eastern North Pacific reveals remarkable similarities in the long-term evolution between GNPIW and EqPIW signatures in the tropical North Pacific during the glacial period. These results support the notion that northern-sourced intermediate water extended further south to the tropical Pacific region than today under glacial boundary conditions. Glacial changes in $\delta^{13}\text{C}$ of sub-thermocline water masses in the EEP were derived from deep-dwelling planktonic foraminiferal species *G. hexagonus* at ODP Site 1240 and indicate significant changes in sub-thermocline water mass characteristics during MIS 2. Notably, the proposed times of additional influence of GNPIW to the tropical Pacific coincides with changes in nutrient availability and biological productivity in the glacial EEP. Overall, our new findings indicate that past changes in North Pacific mid-depth circulation might have played a crucial role in glacial nutrient availability and biological productivity in the EEP, but needs to be further constrained by future studies investigating glacial changes in utilization of major nutrients, such as silicon or iron in the subarctic Pacific.

Acknowledgments and Data

The Helmholtz Climate Initiative REKLIM (Regional climate change) funded this study. NR, LLJ and RT received funding through research projects Manihiki II (03G0225B) and SiGePAX (03F0704A) by the Bundesministerium für Bildung und Forschung (BMBF). This research used samples provided by BMBF-project KALMAR, and the International Ocean Discovery Program (IODP). IODP was sponsored by the U.S. National Science Foundation (NSF) and participating countries under the management of Joint Oceanographic Institutions (JOI), Inc. We gratefully acknowledge the Master and crew of R/V SONNE cruises SO201-2 (KALMAR) and thank for their professional support on board. We express our thanks to L. Schönborn and G. Meyer for conducting stable isotope measurements at the AWI stable isotope lab. The authors thank Isabel Cacho for helpful comments and suggestions. Supplementary data are available at PANGAEA Data Publisher for Earth & Environmental Science.

to be submitted to Paleoceanography

Abstract

The Eastern Equatorial Pacific (EEP) is a key area to understand past oceanic processes that control atmospheric CO₂ concentrations. Many studies argue for higher past nutrient concentrations in the EEP by enhanced transfer of nutrients via Southern Ocean Intermediate Water (SOIW) to the low-latitude Pacific. Latest studies, however, argue against SOIW as a nutrient source at least during Marine Isotope Stage 2 (MIS 2) as proxy-data indicate that nutrients are better utilized in the Southern Ocean under glacial conditions. Whereas, recent results from the subarctic Pacific suggest that enhanced ventilation of nutrient-rich Glacial North Pacific Intermediate Water (GNPIW) contribute to the nutrient concentration in equatorial Pacific sub-thermocline water masses during MIS 2. However, the interplay between SOIW versus GNPIW and its influence on the nutrient distribution in the EEP spanning more than one glacial cycle are still not understood. We present a carbon isotope ($\delta^{13}\text{C}$) study of sub-thermocline waters derived from deep

dwelling planktonic foraminifera *Globorotaloides hexagonus* in the EEP (ODP Site 1240), which is compared with published $\delta^{13}\text{C}$ records around the Pacific. Results indicate an enhanced influence of GNPIW during MIS 2 and MIS 6 compared to today and largest contributions of northern-sourced intermediate waters during glacial maxima. These observations suggest that changes in EEP nutrient concentrations are possibly related to the relative contributions between northern and southern intermediate waters. A switch from increased GNPIW – decreased SOIW to diminished GNPIW – enhanced SOIW influence on equatorial sub-thermocline waters is recognized during glacial terminations and marks substantial changes in nutrient concentrations and biological productivity in the EEP.

5.1 Introduction

The modern Eastern Equatorial Pacific (EEP) acts as the most important source for marine carbon dioxide (CO_2) to the atmosphere [Takahashi et al., 2009]. The elevated pCO_2 has been attributed to the upwelling of nutrient-rich waters in combination with low productivity by siliceous phytoplankton that sequesters CO_2 during photosynthesis [Dugdale and Wilkerson, 1998]. However, primary productivity of these organisms is nowadays hindered by the low availability of silicic acid ($\text{Si}(\text{OH})_4$) and iron in the EEP [Broecker and Peng, 1982; Dugdale et al., 2002; Sarmiento et al., 2004; Ryan et al., 2006]. Other macronutrients such as nitrate are not fully utilized and remain high [Robinson et al., 2009]. Southern Ocean Intermediate Water (SOIW), which is the main contributor of Equatorial Pacific Intermediate Water (EqPIW) under modern conditions [Goodman et al., 2005; Qu et al., 2009; Bostock et al., 2010], only contains depleted $\text{Si}(\text{OH})_4$ concentrations relative to other macronutrients, as diatoms blooming in the formation area of SOIW remove $\text{Si}(\text{OH})_4$ out of the surface waters [Hendry and Brzezinski, 2014]. These low-silicon SOIW are then fed into the low-latitude thermocline [Qu and Lindstrom, 2004]. As a result, SOIW contributes about half of the nitrate supply but only roughly 30 % of the total modern equatorial $\text{Si}(\text{OH})_4$ supply into the EEP upwelling system [Sarmiento et al., 2004; Dugdale et al., 2002]. Its northern counterpart, the nutrient-elevated North Pacific Intermediate Water (NPIW), is nowadays mostly bound to about 20°N but extends further south in the western Pacific [Bostock et al., 2010]. Thereby, the imprint of NPIW reaches the equatorial Pacific, where it accounts for ~70 % of the $\text{Si}(\text{OH})_4$ supply today [Sarmiento et al., 2004].

Under glacial conditions, changes in nutrient utilization based on silicon isotope records showed that the EEP received three times more $\text{Si}(\text{OH})_4$, thereby removing the $\text{Si}(\text{OH})_4$ -limitation within the EEP [Pichevin et al., 2009]. Brzezinski et al. [2002] and Matsumoto et al. [2002b] assumed that excess $\text{Si}(\text{OH})_4$ has been delivered via enhanced SOIW to the EEP as described in the Silicic Acid Leakage Hypothesis (SALH). This caused diatoms to displace coccolithophores at low latitudes and consequently, weakened the carbonate pump and lowered glacial atmospheric pCO_2 [Brzezinski et al., 2002]. Stable isotope analyses [Pena et al., 2008], biomarkers [Calvo et al., 2011], planktonic foraminiferal abundances [Yu et al., 2012], neodymium isotope records (ϵ_{Nd})

[Pena *et al.*, 2013], and radiocarbon data [de la Fuente *et al.*, 2015] further support the increasing influences of southern-sourced waters on the equatorial upwelling waters. However, the potential of SOIW in delivering more nutrients to the low-latitude Pacific under glacial conditions is still under debate. Recent studies found increased glacial productivity in the Southern Ocean, which potentially leave surface waters rather nutrient depleted, and leads to “nutrient-trapping” in the Southern Ocean [Loubere *et al.*, 2011; Hendry and Brzezinski, 2014; Robinson *et al.*, 2014; Rousseau *et al.*, 2016]. Furthermore, there is growing debate on the amount of SOIW formed during glacial maxima. An authigenic mineral study found higher oxygen concentrations along the Chilean margin during glacials and correlated these to an increased SOIW production [Muratli *et al.*, 2010]. In contrast, a benthic carbon isotope ($\delta^{13}\text{C}$) record from the southwest Pacific [Pahnke and Zahn, 2005] and ϵ_{Nd} values from the tropical Atlantic [Pahnke *et al.*, 2008; Huang *et al.*, 2014] both suggest a reduced production of SOIW during glacial conditions, possibly related to stronger water column stratification. More recently, results from benthic $\delta^{13}\text{C}$ records, which form an intermediate to deep water transect at the New Zealand margin, suggest in combination with model results a shoaling of the SOIW / Upper Circumpolar Deep Water (UCDW) boundary during glacials due to an increased freshwater flux into SOIW by melting sea ice [Ronge *et al.*, 2015].

In the subarctic Pacific, benthic foraminiferal $\delta^{13}\text{C}$ records point to increased formation of Glacial North Pacific Intermediate Water (GNPIW) [Duplessy *et al.*, 1988; Keigwin, 1998; Matsumoto *et al.*, 2002a]. In comparison with the modern situation, a ϵ_{Nd} record proposes a glacial shift in the formation area from mainly the Sea of Okhotsk towards the northwest Bering Sea [Horikawa *et al.*, 2010], which was further supported by foraminiferal isotope studies [Rella *et al.*, 2012; Max *et al.*, 2014; Knudson and Ravelo, 2015a; Max *et al.*, under review, *this thesis*] and reconstructions based on radiolarian assemblages [Matul *et al.*, 2015]. Evidence for strengthened mid-depth circulation in the North Pacific has been further noticed along the California margin to the Eastern Tropical North Pacific (ETNP) [Stott *et al.*, 2000; Leduc *et al.*, 2010] and as far as the equatorial Pacific, where benthic $\delta^{13}\text{C}$ signatures and trends show apparent similarities between Bering Sea records and EEP sub-thermocline waters during glacial boundary conditions [Knudson and Ravelo, 2015a; Max *et al.*, under review, *this thesis*].

First studies indicate reoccurring signals during the Pleistocene with a shallower penetration of SOIW in the southern hemisphere and at the same time higher GNPIW ventilation in the North Pacific [Elmore *et al.*, 2015; Knudson and Ravelo, 2015a; Ronge *et al.*, 2015]. However, the interplay between SOIW versus NPIW and its influence on past nutrient distribution in the EEP spanning more than one glacial cycle are not well constrained, but important for our understanding of past ocean processes and past atmospheric CO_2 fluctuations. This study provides new insights into the dynamic behaviour by comparing $\delta^{13}\text{C}$ records from the equatorial sub-thermocline Pacific, the Pacific Sector of the Southern Ocean and the North Pacific to further disentangle the varying sources of nutrient-injections into the equatorial Pacific sub-thermocline over the past 240 ka.

5.1.1 Modern oceanography and hydrography

The modern EEP is one of the largest high-nitrate low-chlorophyll (HNLC) areas in the world oceans [e.g. *Dugdale and Wilkerson, 1998; Le Borgne et al., 2002*]. Delivery of nutrients towards the EEP happens through the eastward flowing Equatorial Undercurrent (EUC) that is formed in the western equatorial Pacific by the South Equatorial Current (SEC), New Guinea Coastal Undercurrent (NGCUC) and the North Equatorial Counter Current (NECC) (Figure 5.1a) [*Fine et al., 1994; Dugdale et al., 2002*]. As the EUC flows eastward across the equatorial Pacific its upper branch shoals parallel with the thermocline providing nutrients to the euphotic zone and thereby, stimulating primary productivity [*Dugdale et al., 2002; Ryan et al., 2006*]. The lower branch of the EUC does not upwell along the equator, but as it travels across the equator it receives nutrients from the underlying EqPIW and at the same time provides nutrients to the upper EUC by diapycnal mixing [*Dugdale et al., 2002; Qu et al., 2009; Rafter and Sigman, 2015*].

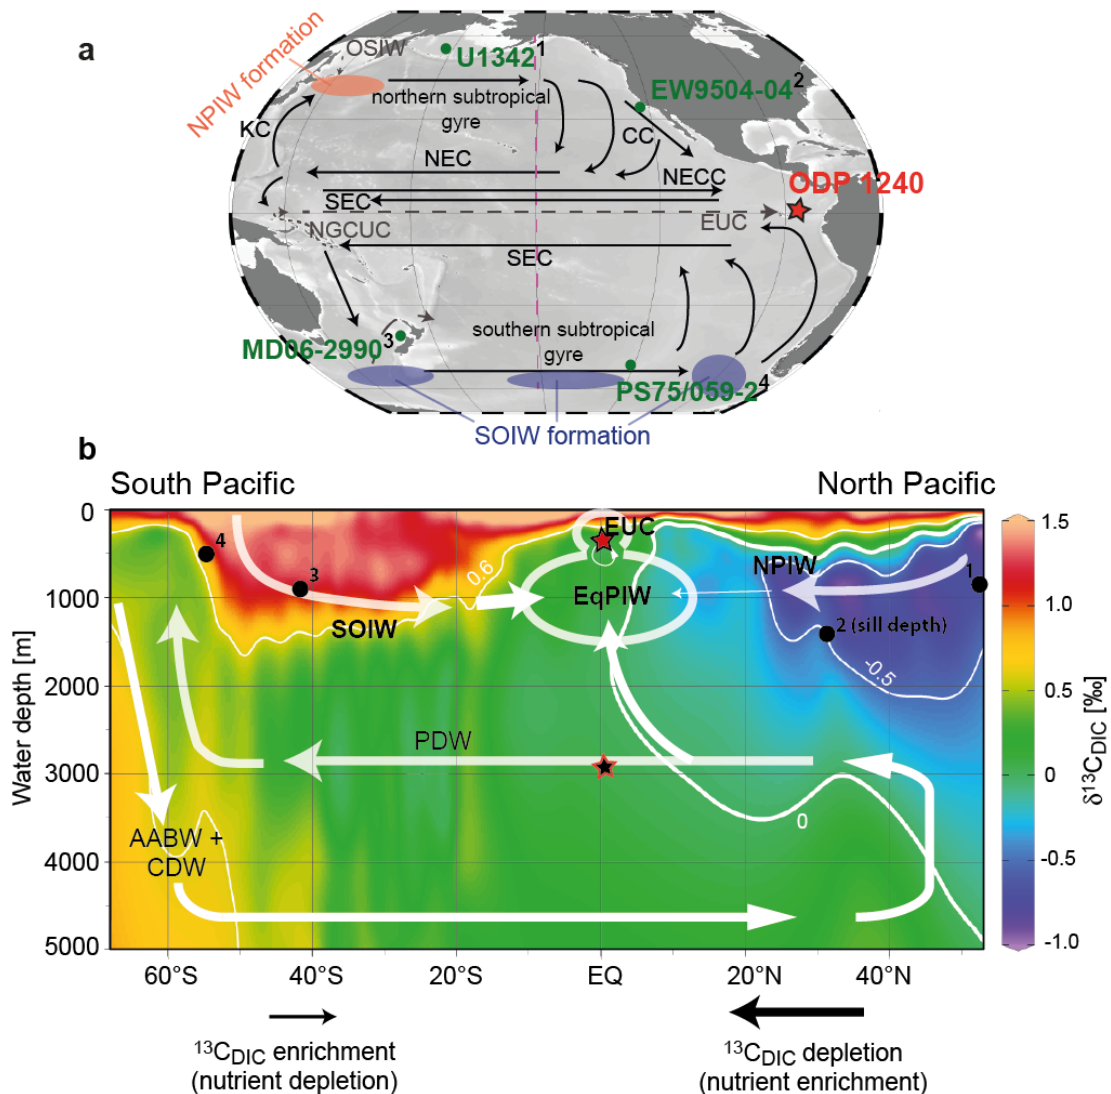

Figure 5.1. Overview of Pacific Ocean current system and hydrography. a: Major surface (solid line) and subsurface (dashed line) currents that are mentioned in the text [after *Tchernia, 1980; Tomczak*

and Godfrey, 2005; Kessler, 2006]. Formation areas of North Pacific Intermediate Water (NPIW) and Southern Ocean Intermediate Water (SOIW) are given in colored circles [after Talley, 1993; Bostock et al., 2013]. Location of sediment core ODP Site 1240 [this study] is shown with a red star, other $\delta^{13}\text{C}$ reference cores with green spots. The red line in (a) denotes the transect shown in (b). b: Meridional carbon isotope transect across the Pacific Ocean with major mid-depth to deep water masses (white arrows): Equatorial Pacific Intermediate Water (EqPIW) and Equatorial Undercurrent (EUC), NPIW and SOIW, PDW = Pacific Deep Water, AABW = Antarctic Bottom Water and CDW = Circumpolar Deep Water. The red star indicates the location of ODP Site 1240 benthic (open) and ODP Site 1240 *G. hexagonus* (full). Black dots denote the reference sediment cores from (a) (assignment through small numbers). Maps and transect were generated using Ocean Data View [Schlitzer, 2015] using data from Schmitter et al. [2013].

In HNLC areas, including the EEP primary productivity is stimulated by the input of iron [e.g. Martin et al., 1994; Coale et al., 1998]. A variety of iron sources in the formation region of the EUC have been identified to increase the iron concentration within the EUC including hydrothermal venting [Gordon et al., 1997], riverine input and direct interaction of NGCUC with continental shelf areas [Mackey et al., 2002] as well as atmospheric dust input along the equator [Winckler et al., 2008]. A nutrient analysis by Dugdale et al. [2002] revealed that concentrations of other macronutrients such as nitrate and $\text{Si}(\text{OH})_4$ are not only asymmetrically distributed along the equator but also differ meridional. North of the equator within the NECC both $\text{Si}(\text{OH})_4$ and nitrate are in about equal proportions. Contrary, the NGCUC has low $\text{Si}(\text{OH})_4$ to nitrate ratios, a signal originating in its source water – the SOIW (Table 5.1) [Dugdale et al., 2002]. SOIW comprises Subantarctic Mode Water (SAMW) and Antarctic Intermediate Water (AAIW) [after Pena et al., 2013]. SAMW occupies ~300 – 800 m water depth and is formed in wintertime by vigorous deep mixing along the Subantarctic Front [McCartney, 1977; Bostock et al., 2013]. The densest of the circumpolar SAMW is the AAIW, which sinks to 800 – 1400 m water depth [McCartney, 1977; Bostock et al., 2013], although characterized by a prominent salinity minimum [McCartney, 1977].

On the other hand, NPIW, which is the main contributor for NECC [Fine et al., 1994], is never exposed to the surface thereby nutrient-depletion by biological productivity is marginal and nutrient levels remain high [Sarmiento et al., 2004]. Instead, modern NPIW-formation is tightly coupled to Okhotsk Sea Intermediate Water (OSIW) that is formed in coastal polynyas during wintertime sea-ice formation within the Sea of Okhotsk [Shcherbina et al., 2003]. The fresh and cold OSIW merges with the northward flowing warm and less dense Kuroshio Current (KC) and forms a mixture of these two water masses east of Japan in the northwest Pacific [Talley, 1993]. The nutrient-elevated NPIW spreads at depths of approximately 300 – 800 m southwards and eastward across the North Pacific (Table 5.1) and feeds the near-surface flowing California Current (CC) as well as North Equatorial Current (NEC) and NECC [Reid, 1965; Talley, 1993].

Equatorial Pacific Intermediate Water that provides nutrients to the overlying EUC is mainly made up of SOIW and Pacific Deep Water (PDW) under modern conditions [Bostock et al.,

2010]. PDW formed initially in the North Pacific via upwelling and diffusion of Circumpolar Deep Water (CDW) and Antarctic Bottom Water (AABW) (Figure 5.1) [Tomczak and Godfrey, 2005]. The deep northern-south water mass is the oldest water mass on Earth, characterized by low oxygen and high nutrient concentrations with a pronounced silicate maximum as well as elevated CO₂ concentrations (Table 5.1) [Fiedler and Talley, 2006].

Table 5.1. Modern geochemical characteristics for different intermediate and deep water-masses at their origin.

| Tracer | NPIW | EUC + EqPIW ^a | SOIW | PDW | AABW |
|--|-------------|--------------------------|-------------|-------------|-------------|
| Salinity ^{1,2} | 33.9 – 34.1 | 34.5 – 34.7 | 34.3 – 34.5 | 34.6 – 34.7 | 34.6 – 34.8 |

5.2 Materials and Methods

5.2.1 Material and stable isotope analyses

We measured stable oxygen ($\delta^{18}\text{O}$) and carbon ($\delta^{13}\text{C}$) isotopes of deep-dwelling planktonic foraminifera *Globorotaloides hexagonus* from ODP Site 1240 at the northern flank of Carnegie Ridge in the Panama Basin (0°01.31'N, 86°27.76'W, 2,921 m water depth) [Mix *et al.*, 2003] (Figure 5.1). For stable isotope analyses, five specimens of *G. hexagonus* were picked from the 250 – 315 μm size fraction in each sample. The measurements were conducted on a Thermo Fisher Scientific MAT 253 mass spectrometer coupled to an automatic carbonate preparation device Kiel CARBO IV at AWI. The isotope measurements were calibrated via the international standard NBS 19 and all results are given in δ -notation versus VPDB. The precision of the measurements, determined over a one-year period and based on repeated analysis of an internal laboratory standard (Solnhofen limestone), is ± 0.06 ‰ and ± 0.08 ‰ for carbon and oxygen isotopes, respectively.

To validate the depth habitat of *G. hexagonus* we determined its Apparent Calcification Depth (ACD) using the uppermost core top sample (at 10 cm) [details described in Max *et al.*, under

review, *this thesis*]. The ACD assessment indicates an ACD of 340 – 430 m water depth that agrees with studies from the central equatorial Pacific [*Rippert et al.*, 2016, *this thesis*] and North Pacific [*Ortiz et al.*, 1996].

We further used published benthic $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ records from Bering Sea sediment core U1342 (54.83°N, 176.92°E, 818 m) [*Knudson and Ravelo*, 2015a] and from South Pacific sediment core SO136-003/MD06-2990 (in the later only termed MD06) (42.19°S, 169.55°E, 943 m) [*Ronge et al.*, 2015].

5.2.2 Stratigraphic approach

We improved existing age models of the first 29 meters composite depth (m.c.d.) from ODP Site 1240 [*Pena et al.*, 2008], MD06 [*Ronge et al.*, 2015] and U1342 [*Knudson and Ravelo*, 2015a] by a combination of published radiocarbon dating (if available) and $\delta^{18}\text{O}$ correlation to the global benthic $\delta^{18}\text{O}$ stack LR04 [*Lisiecki and Raymo*, 2005] (Figure 5.2). For the age model of ODP Site 1240, we used the established age model from *Pena et al.* [2008] for the first 5.2 m.c.d. based on 17 Accelerator Mass Spectrometry (AMS) ^{14}C dates that cover the first ~38 ka. For the sediment depth interval between 5.2 m.c.d. and ~19 m.c.d. we used a new benthic $\delta^{18}\text{O}_{\text{Cibicidoides}}$ record and $\delta^{18}\text{O}$ record of deep-dwelling planktonic foraminifera *G. hexagonus* [both *this study*], which were aligned graphically to the LR04 record [*Lisiecki and Raymo*, 2005]. Beyond the range of the $\delta^{18}\text{O}_{\text{Cibicidoides}}$ record (~19 m.c.d. – 29.4 m.c.d.), we took the *G. hexagonus* record and visually tuned it to the LR04 stack. As the *G. hexagonus* record has a only low-resolution during that time interval, we additionally used the surface-dwelling planktonic species *Globigerinoides ruber* record of ODP Site 1240 [*Pena et al.*, 2008] to constrain the developed age model (Figure 5.2). Furthermore, the ash layer “L” [*Ninkovich and Shackleton*, 1975] was considered as well that is located at 125.71 m.c.d. [*Pena et al.*, 2008]. Our age model estimation yields an age of the ash layer “L” of 235.83 ka, which is in the range of the previously estimated age of 230 ± 10 ka [*Ninkovich and Shackleton*, 1975].

For the age model of site MD06 we used the six ^{14}C dates of *Ronge et al.* [2015] dating back ~25 ka and beyond that graphically tuned the benthic *Cibicidoides wuellerstorfi* $\delta^{18}\text{O}$ record to the LR04 record. For U1342 we used the $\delta^{18}\text{O}$ values measured on *Uvigerina peregrina* [*Knudson and Ravelo*, 2015a] and graphically aligned them to LR04.

As a result, the sediment record from 0 – 29.4 m.c.d. of ODP Site 1240 comprises the time interval of the last 300 kyrs. The sampling distance provides an average time resolution of 0.23 kyr for the first 60 ka and 1.4 kyr for 60 – 240 ka. The upper 9.4 m of sediment core MD06 and the upper 39.4 m of U1342 (core composite depth below seafloor, CCSF-A) cover the time interval of the last 351.7 kyr and 1260 kyr with an average temporal resolution of 0.91 kyr and 1.16 kyrs, respectively (Figure 5.2). Supplementary Table S5.7.1 summarizes all age control points used for site ODP Site 1240, MD 06, and U1342.

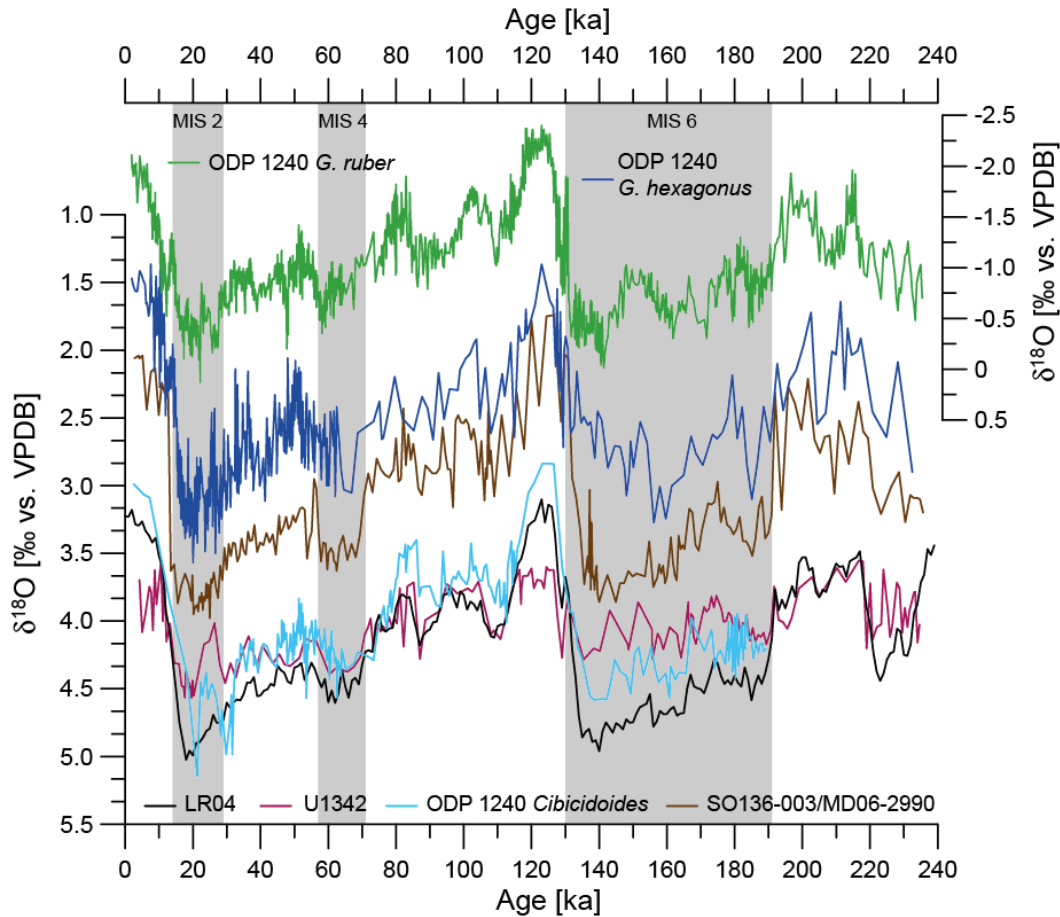

Figure 5.2. Stratigraphic correlation of published and newly generated $\delta^{18}\text{O}$ records with respect to the benthic $\delta^{18}\text{O}$ reference stack (LR04, black) [Lisiecki and Raymo, 2005]. ODP Site 1240 *G. ruber* (green) [Pena et al., 2008], ODP Site 1240 *G. hexagonus* (dark blue) [this study], SO136-003/MD06-2990 *C. wuellerstorfi* (brown) [Ronge et al., 2015], ODP Site 1240 *Cibicidoides* spp. (light blue) [this study] and U1342 *U. peregrina* (purple) [Knudson and Ravelo, 2015a].

5.3 Carbon isotopes as proxy for nutrient concentrations

Over the past decades it has been shown that the $\delta^{13}\text{C}$ signature of specific benthic foraminiferal tests is closely related to the $\delta^{13}\text{C}_{\text{DIC}}$ signature of ambient seawater [Berger et al., 1978; Duplessy et al., 1988]. This makes foraminiferal $\delta^{13}\text{C}$ a widely applied proxy to trace past changes in circulation and nutrient conditions in the global ocean [Duplessy et al., 1984; Oppo and Fairbanks, 1990; Mix et al., 1991; Zahn et al., 1991; Keigwin, 1998; Stott et al., 2000; Matsumoto et al., 2002a; Curry and Oppo, 2005; Rickaby and Elderfield, 2005; Bostock et al., 2010; Knudson and Ravelo, 2015a].

In this study we compare the epibenthic *C. wuellerstorfi* and infaunal *U. peregrina* with the sub-thermocline dwelling planktonic species *G. hexagonus*. Differences in species habitat or ecology might affect the $\delta^{13}\text{C}$ interpretation. *C. wuellerstorfi* lives epibenthic or elevated above the sediment surface [Lutze and Thiel, 1989] and its calcitic test has been shown to reliably record

the $\delta^{13}\text{C}_{\text{DIC}}$ signal without significant fractionation of carbon isotopes [Duplessy *et al.*, 1984]. The influence of seasonal depositions of phytodetritus layers might affect the $\delta^{13}\text{C}$ of benthic foraminifera [Mackensen *et al.*, 1993]. However, this influence was excluded for MD06 due to negligible glacial-interglacial changes in paleoproductivity [Ronge *et al.*, 2015]. In contrast, infaunal *U. peregrina* was found to correlate with accumulation rates of organic carbon, which leads to a disequilibrium from bottom water $\delta^{13}\text{C}_{\text{DIC}}$ [Zahn *et al.*, 1986]. In this study, we used the corrected *U. peregrina* values from Knudson and Ravelo [2015a], who converted the $\delta^{13}\text{C}_{U.peregrina}$ values to $\delta^{13}\text{C}_{C.wuellerstorfi}$ values by using a constant adjustment of +0.9 ‰. However, this offset was shown to be highly variable ranging from +1.1 ‰ during the Holocene to +0.1 ‰ during MIS 2 around New Zealand [McCave *et al.*, 2008]. It was found to be even larger (+1.4 to +0.76 ‰) in a more recent study from the same area [Elmore *et al.*, 2015]. Nevertheless, an adjusted correction factor would change the amplitude but not the direction of the curve. Given, that there are no studies available from the subarctic Pacific that determine the variable offset between *Cibicidoides* and *Uvigerina*, we refrained from using a variable $\delta^{13}\text{C}$ offset factor and used the correction for *U. peregrina* values given by Knudson and Ravelo [2015a]. For planktonic *G. hexagonus* we assume a constant calcification depth over time. Further, we do not correct $\delta^{13}\text{C}$ values of *G. hexagonus* for disequilibrium effects as the few available studies infer an only marginal carbon isotope offset to ambient $\delta^{13}\text{C}_{\text{DIC}}$ [Birch *et al.*, 2013; Rippert *et al.*, 2016, *this thesis*].

Intermediate and deep water masses from different end-members have a characteristic $\delta^{13}\text{C}_{\text{DIC}}$ signature (Figure 5.1b, Table 5.1), depending on the biological cycle and thermodynamically driven gas exchange between the surface ocean and the atmosphere [Mackensen *et al.*, 1993; Rohling and Cooke, 1999; Lisiecki, 2010; Mackensen, 2012]. The latter is particularly important in the source region of intermediate waters; with each 1°C drop in temperature, the $\delta^{13}\text{C}_{\text{DIC}}$ decreases by 0.1 ‰ [Broecker and Maier-Reimer, 1992; Mackensen, 2012]. In the Southern Ocean, the glacial drop in $\delta^{13}\text{C}$ of intermediate waters is similar to the $\delta^{13}\text{C}$ drop recorded in UCDW, thus it was assumed that the thermodynamic effect influences the $\delta^{13}\text{C}$ record only insignificantly [Ronge *et al.*, 2015]. In the subarctic Pacific, the modern and glacial formation of intermediate waters is linked to sea-ice formation when surface-ocean temperatures are close to the freezing point [Rella *et al.*, 2012]. Given that the formation conditions are nearly congruent during glacial-interglacials, a change in the air-sea gas exchange is assumed to have an only minor effect on the $\delta^{13}\text{C}$ signal of the Bering Sea.

Nevertheless, instead of using absolute $\delta^{13}\text{C}$ values, we adopted the approach by Knudson and Ravelo [2015a] and used the comparisons between ODP Site 1240 with U1342_{*U.peregrina* (corr.)} [Knudson and Ravelo, 2015a] and MD06 [Ronge *et al.*, 2015] as a proxy for relative nutrient injections of northern-sourced and southern-sourced waters on equatorial sub-thermocline. Thus, as a proxy for assessing GNPIW-nutrient influence we calculate $\Delta\delta^{13}\text{C}_{\text{NP-EQ}_{G.hex}}$ ($\delta^{13}\text{C}$ at site U1342 minus $\delta^{13}\text{C}_{G.hex}$ at ODP Site 1240) and for SOIW-nutrient influence the $\Delta\delta^{13}\text{C}_{\text{EQ}_{G.hex}\text{-SP}_{SW}}$ (the $\delta^{13}\text{C}_{G.hex}$ at site ODP Site 1240 minus $\delta^{13}\text{C}$ at MD06). In the modern ocean, U1342 is located in 818 m water depth within the oxygen minimum zone, which is characterized by very low $\delta^{13}\text{C}$

values (Figure 5.1b). On the other hand, *G. hexagonus* of ODP Site 1240 is situated in ^{13}C enriched (nutrient-depleted) waters that are mainly fed from southern-sourced waters today [Bostock *et al.*, 2010]. Consequently, modern $\Delta\delta^{13}\text{C}_{\text{CNP-EQ}_{G.\text{hex}}}$ values are extremely negative. If the oxygen minimum zone at site U1342 is replaced by well-ventilated GNPIW, the benthic foraminifers would bath in relatively high $\delta^{13}\text{C}_{\text{DIC}}$ signatures. If GNPIW expands its influence southward into the EEP upwelling system, the equatorial and the subarctic $\delta^{13}\text{C}$ values would approach each other. A full control of GNPIW on equatorial sub-surface water would result in a small but still positive difference ($\Delta\delta^{13}\text{C}_{\text{CNP-EQ}_{G.\text{hex}}}$), allowing for the aging effect on the $\delta^{13}\text{C}$ signal. To investigate the SOIW- influence we use the same approach. In the modern ocean SOIW has relatively high $\delta^{13}\text{C}_{\text{DIC}}$ values (Figure 5.1b) and the $\delta^{13}\text{C}$ difference between equatorial sub-thermocline and SOIW is relatively small. If the injection of SOIW into the EEP upwelling system would cease, we would expect an increased difference in $\delta^{13}\text{C}$ (large $\Delta\delta^{13}\text{C}_{\text{EQ}_{G.\text{hex}}-\text{SP}_{\text{SW}}}$).

5.4 Results

Over the last 240 ka carbon isotope data from North Pacific core U1342, equatorial sub-thermocline (ODP Site 1240 *G. hexagonus*) and South Pacific record MD06 oscillate between -0.68 ‰ and +1.38 ‰ with high $\delta^{13}\text{C}$ and thus, nutrient-depleted values in the South Pacific and low $\delta^{13}\text{C}$ (nutrient-elevated) values in the North Pacific (Figure 5.3).

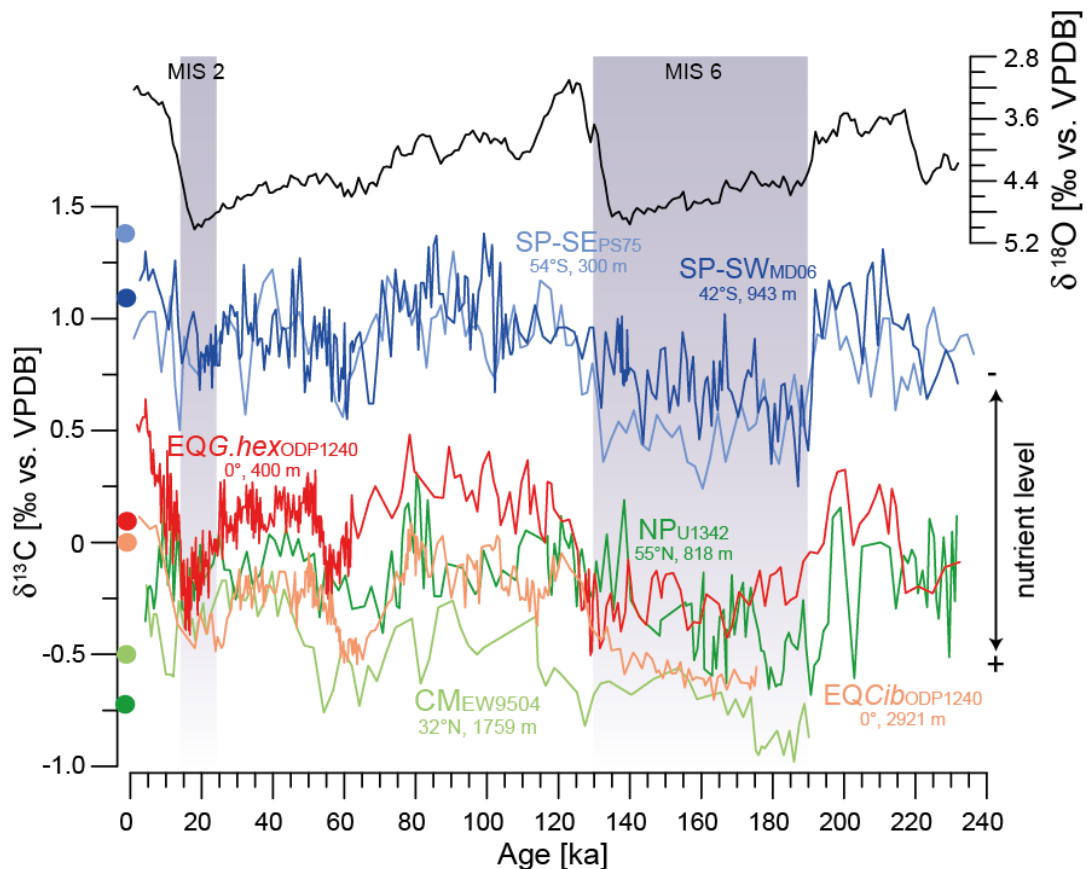

Figure 5.3. Compilation of Pacific carbon isotope records: MD06 (South Pacific) (dark blue) [Ronge *et al.*, 2015], PS75/059-2 (light blue) [Tapia, 2016], equatorial ODP Site 1240 *G. hexagonus* (red) and

Cibicidoides (orange) [*this study*], U1342_{corr.} (North Pacific) (dark green) [*Knudson and Ravelo, 2015a*] and EW9504-04 (California margin (CM), light green) [*Stott et al., 2000*]. Benthic $\delta^{18}\text{O}$ stack [*Lisiecki and Raymo, 2005*] is shown for stratigraphic orientation. Coloured circles denote modern $\delta^{13}\text{C}_{\text{DIC}}$ at core location. Grey bars mark glacial Marine Isotope Stages 2 and 6.

The $\delta^{13}\text{C}$ amplitude in all three records is similar (0.99 – 1.14 ‰) and do not differ significantly. In every record, glacial periods are characterized by lower and interglacial by higher $\delta^{13}\text{C}$ values displaying the 0.32 ‰ changes in the terrestrial biosphere and consequently storage in the deep ocean [*Gebbie et al., 2015*] as well as additional changes in the ocean interior. Equatorial sub-thermocline $\delta^{13}\text{C}$ variations are assumed to reflect both nutrient injections and export productivity in the surface ocean of the EEP. Late Holocene equatorial sub-thermocline values largely follow South Pacific signatures and drift apart from North Pacific values (Figure 5.3). Contrary, equatorial sub-thermocline $\delta^{13}\text{C}$ values show an apparent similarity with North Pacific $\delta^{13}\text{C}$ record during glacial periods and particularly during the glacial maxima MIS 2 and MIS 6.

5.5 Discussion

The carbon isotope comparisons ($\Delta\delta^{13}\text{C}$) between the North Pacific and EEP sub-thermocline as well as between EEP sub-thermocline and the South Pacific allow us to identify relative changes in the nutrient input into equatorial sub-thermocline waters. Modern $\Delta\delta^{13}\text{C}_{\text{EQ}_{\text{G.hex}}-\text{SP}_{\text{SW}}}$ values are very negative (-1.0 ‰) albeit SOIW largely contributes to equatorial sub-thermocline waters under modern conditions [*Bostock et al., 2010*]. Contrary, modern $\Delta\delta^{13}\text{C}_{\text{NPN}-\text{EQ}_{\text{G.hex}}}$ values are slightly more positive than $\Delta\delta^{13}\text{C}_{\text{EQ}_{\text{G.hex}}-\text{SP}_{\text{SW}}}$, although northern-sourced waters only subsidize minor to equatorial sub-thermocline waters today. This contrasting picture might be explained by the additional contribution of $\delta^{13}\text{C}$ -depleted PDW on equatorial sub-thermocline that would decrease equatorial $\delta^{13}\text{C}$ values [*Bostock et al., 2010*]. During the past 240 ka and particularly during late MIS 2 (16 – 19 ka) and late MIS 6 (128 – 140 ka) both $\Delta\delta^{13}\text{C}$ curves show large-scale fluctuations (Figures 5.4c and d), which indicate that the source water-mass contribution might have been different in the past.

5.5.1 Reduced SOIW-nutrient contribution on equatorial sub-thermocline during peak glacials

In a first step, we investigated the relative nutrient-contribution of southern-sourced water masses on equatorial sub-thermocline, as the majority of modern equatorial waters are fed by SOIW [*Bostock et al., 2010*]. The $\delta^{13}\text{C}$ difference between the southwestern South Pacific and equatorial sub-thermocline record ($\Delta\delta^{13}\text{C}_{\text{EQ}_{\text{G.hex}}-\text{SP}_{\text{SW}}}$) increased from -1.0 ‰ under modern conditions to -1.2 ‰ during glacial maxima (Figure 5.4). This increasing $\delta^{13}\text{C}$ difference suggests that southern-sourced water masses are either more nutrient-depleted compared to today or that the

Figure 5.4. Comparison of different $\delta^{13}\text{C}$ records from the Pacific. a: Global benthic $\delta^{18}\text{O}$ stack [Lisiecki and Raymo, 2005] for stratigraphic reference, b: ϵ_{Nd} record from Bering Sea core BOW-8A [Horikawa et al., 2010], c: 5pt moving average of $\delta^{13}\text{C}$ comparison between North Pacific sediment core U1342 (NP) [Knudson and Ravelo, 2015a] and California Margin (CM) record EW9504-04 [Stott et al., 2000] minus ODP Site 1240 *G. hexagonus* values. d: 5pt moving average of $\delta^{13}\text{C}$ comparison between ODP Site 1240 *G. hexagonus* values minus southeast Pacific record PS75-59-2 (SP_{SE}) [Tapiá, 2016] and southwest Pacific MD06 (SP_{SW}) [Ronge et al., 2015]. Colored circles denote $\Delta\delta^{13}\text{C}$ values using modern water mass characteristics for the respective comparisons. Grey bars denote glacial Marine Isotope Stages 2 and 6.

nutrient-injection from SOIW derived in the southwestern Pacific into the equatorial intermediate water is reduced during peak glacials. However, different formation regions of SOIW exist in the South Pacific (Figure 5.1a) with the bulk of SOIW formed in the southeast Pacific off Chile [Bostock et al., 2013]. This southeast-SOIW is slightly younger and fresher than the SOIW-counterpart in the southwest Pacific [Bostock et al., 2013]. Higher glacial oxygen concentrations along the Chilean margin were correlated to an enhanced SOIW formation in the SE Pacific dur-

ing the Last Glacial Maximum (LGM) [Muratil *et al.* [2010]. Unfortunately, hardly any sediment cores from intermediate depths recording long-term variations in intermediate water $\delta^{13}\text{C}_{\text{DIC}}$ exist from the southeast Pacific. We therefore considered a central South Pacific $\delta^{13}\text{C}$ record from the deep-dwelling planktonic foraminifera *Globorotalia inflata* (core PS75/059–2; 54°13'S, 125°256'W, 3.613 m water depth; Tapia [2016]), that calcifies in 300 – 800 m water depth and thus, within SOIW (Figure 5.1c) [Elderfield and Ganssen, 2000; Tapia, 2016]. Carbon isotope values were corrected by +0.3 ‰ as *G. inflata* calcifies in disequilibrium with ambient seawater [King and Howard, 2004; Shiraldi *et al.*, 2014]. The $\delta^{13}\text{C}$ values of PS75/059-2 (SP-SE_{PS75}) display comparable values as $\delta^{13}\text{C}_{\text{MD06}}$ (Figure 5.3). This indicates that the nutrient composition of intermediate waters from the eastern and western sector of the South Pacific is rather similar across the Pacific Sector of the Southern Ocean. Accordingly, the $\delta^{13}\text{C}$ difference of $\Delta\delta^{13}\text{C}_{\text{EQ}_{\text{G.hex}}-\text{SP}_{\text{SE}}}$ shows a similar pattern as $\Delta\delta^{13}\text{C}_{\text{EQ}_{\text{G.hex}}-\text{SP}_{\text{SW}}}$ (Figure 5.4d).

The $\delta^{13}\text{C}$ values of the penultimate glacial in both southeast and southwest Pacific cores are lower than the respective $\delta^{13}\text{C}$ values of MIS 2 (Figure 5.3). In the southwest Pacific, the $\Delta\delta^{13}\text{C}_{\text{EQ}_{\text{G.hex}}-\text{SP}_{\text{SW}}}$ values display comparable signatures during MIS 2 and MIS 6 (Figure 5.4). In contrast, in the southeast Pacific the $\Delta\delta^{13}\text{C}_{\text{EQ}_{\text{G.hex}}-\text{SP}_{\text{SE}}}$ values are offset by ~ 0.2 ‰ between MIS 2 and MIS 6. Only during peak MIS 2 and peak MIS 6, they display similar values. A local salinity reconstruction from the central south Pacific estimated that contrasting conditions prevailed in the Southern Ocean between MIS 2 and MIS 6 with water masses saltier than during the Holocene during MIS 6 and contrasting fresher-than-Holocene conditions during MIS 2 [Tapia *et al.*, 2015]. To what extent this might influence the nutrient concentration between the southeast and southwest Pacific Ocean remains elusive as information regarding major nutrient cycles are missing during MIS 6. Nevertheless, the last peak glacial and the penultimate glacial shows an increased difference between equatorial sub-thermocline waters and SOIW waters compared to modern values.

Our analyses point to a reduced southern nutrient-contribution on equatorial sub-thermocline during high glacials. This notion is supported by $\delta^{13}\text{C}$ studies from New Zealand, that highlight a shoaling of the SOIW/UCDW boundary from ~ 2000 m to ~ 1100 m water depth [Elmore *et al.*, 2015; Ronge *et al.*, 2015]. This shoaling possibly reflect a reduced production of SOIW due to increased freshwater flux by melting sea ice in the formation area of SOIW [Pahnke and Zahn, 2005; Ronge *et al.*, 2015]. Further support comes from nutrient studies in the Southern Ocean that found increased opal accumulation rates in the Subantarctic Zone (SAZ) during glacials, which was explained by an increased upwelling due to enhanced wind stress in the SAZ and thus, a higher supply of nutrients to the euphotic zone [Hendy and Brzezinski, 2014; Robinson *et al.*, 2014]. As a consequence, the nutrient-concentration of SOIW decreased during glacials. Thus, it seems questionable whether nutrient-depleted SOIW was able to stronger enhance productivity at the equator during late MIS 2 and late MIS 6 as suggested by proxies indicative of changes in biological productivity. Opal flux and productivity reconstructions in the EEP infer a

greater nutrient contribution during glacials [e.g. *Dugdale et al.*, 2004; *Loubere et al.*, 2003, 2007; *Calvo et al.*, 2011; *Loubere et al.*, 2011], which suggest that sub-thermocline waters in the EEP experienced substantial changes in its chemistry. Thus, the largest $\delta^{13}\text{C}$ difference between the EEP and Southern Ocean $\delta^{13}\text{C}$ values argues for a relative reduced contribution of nutrient-depleted southern-sourced waters on equatorial sub-thermocline during extreme glacials (Figure 5.5).

5.5.2 Northern-sourced nutrient influence on EqPIW during peak glacials

Here we consider two possible sourced from the North Pacific, PDW and NPIW. The change in $\delta^{13}\text{C}_{G.hexagonus}$ values during the peak glacials might be explained by an enhanced upwelling of PDW at the equator. A recent ϵ_{Nd} data comparison between LGM and Holocene values reveals substantial reduced glacial ϵ_{Nd} values in the EEP, which was explained by a more invigorated deep circulation and higher contribution from deep northern-sourced waters [*Hu et al.*, 2016]. Sediment core ODP Site 1240 was retrieved from ~2900 m water depth and thus, the benthic $\delta^{13}\text{C}$ of ODP Site 1240 reports variability in PDW waters (Figure 5.1). The comparison between the *G. hexagonus* record and the benthic record of ODP Site 1240 yields an offset of ~0.2 ‰ during late MIS 2 and MIS 6, when the $\delta^{13}\text{C}$ differences between the equatorial sub-thermocline and the Southern Ocean is greatest (Figure 5.3). The $\delta^{13}\text{C}_{G.hexagonus}$ and $\delta^{13}\text{C}_{Cibicoides}$ values approach each other only during the Termination I and II. They indicate even similar values during Termination II (126 – 132 ka) after the maximum $\delta^{13}\text{C}$ difference between the EqPIW and SOIW occurred (Figures 5.3 and 5.4). Thus, we argue that the glacial PDW contribution into the sub-thermocline might not have changed substantially from today's (Figure 5.5). Only during the deglaciation, the contribution from deep water masses on the equatorial sub-thermocline might have been enhanced. This notion is supported by a recent $\delta^{13}\text{C}$ comparison between EqPIW and PDW during the past 60 ka, which indicates a substantially different temporal evolution in $\delta^{13}\text{C}$ values of EqPIW and PDW during MIS 2 [*Max et al.*, under review, *this thesis*]. Furthermore, recent analyses of radiocarbon activity show maximal benthic ^{14}C offsets to atmospheric values during the LGM [*Skinner et al.*, 2010; *de la Fuente et al.*, 2015; *Skinner et al.*, 2015; *Ronge et al.*, 2016]. At 15 ka, within the termination when both our determined $\delta^{13}\text{C}_{EQG.hex-SP}$ offsets decrease (Figure 5.3), the old glacial carbon pool between 2000 – 4300 m was eroded [*Ronge et al.*, 2016]. The decreasing ventilation ages were explained by the deglacial breakdown of the Southern Ocean stratification in relation to enhanced Southern Ocean upwelling [*Ronge et al.*, 2016]. Also within the EEP, a ventilation age reconstruction from ODP Site 1240 estimated that the largest benthic-planktonic ^{14}C offset (B-P) occurred during peak MIS 2, which decreased to modern values from 15 ka onward [*de la Fuente et al.*, 2015]. These combined evidences argue against a higher PDW contribution to EEP sub-thermocline waters during peak glacials and rather suggests a more invigorated role of northern-sourced intermediate waters.

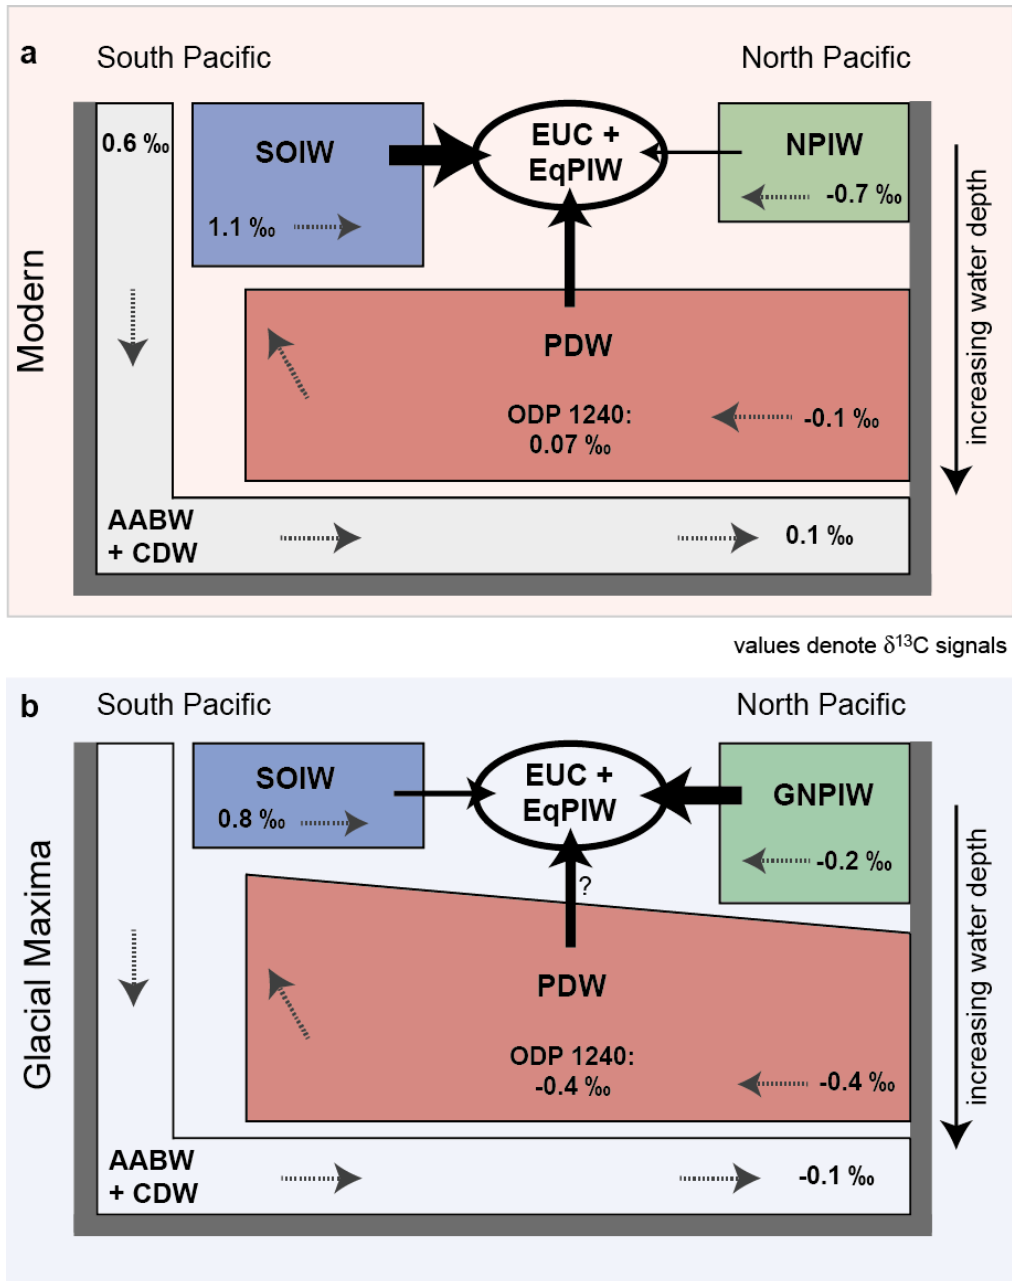

Figure 5.5. Schematic illustration of changing end-member contributions on EEP upwelling waters during a: interstadials and b: glacial maxima. EUC + EqPIW = Equatorial Undercurrent + Equatorial Pacific Intermediate Water, SOIW = Southern Ocean Intermediate Water, (G)NPIW = (Glacial) North Pacific Intermediate Water, PDW = Pacific Deep Water, CDW + AABW = Antarctic Bottom Water + Circumpolar Deep Water. Black arrows represent possible contributions of end-members and dashed arrows show current flow. Given values represent $\delta^{13}\text{C}$ values that were determined using data from GLODAP [Key *et al.*, 2004], Peterson *et al.* [2014], and from sediment cores analyzed in this study.

In a next step, we compared the $\delta^{13}\text{C}$ sub-thermocline values to a record from the Bering Sea (U1342) to investigate a possible contribution of GNPIW. Our $\delta^{13}\text{C}$ comparison reveals that the difference between the Bering Sea and EEP $\delta^{13}\text{C}$ values ($\Delta\delta^{13}\text{C}_{\text{NP-EQ}_{G,\text{hex}}}$) diminishes substantially during glacials and both $\delta^{13}\text{C}$ records approach similar values during late MIS 2 and late

MIS 6. Most interestingly, the smallest offset between $\delta^{13}\text{C}_{\text{NP}}$ and $\delta^{13}\text{CEQ}_{\text{G.hex}}$ values happen simultaneously to the largest offset between $\delta^{13}\text{CEQ}_{\text{G.hex}}$ and $\delta^{13}\text{C}_{\text{SP}}$ signatures (Figure 5.4). This might indicate a relatively higher GNPIW contribution than today on the equatorial $\delta^{13}\text{C}$. Given that GNPIW evinces slightly higher $\delta^{13}\text{CEQ}_{\text{G.hex}}$ values, the $\Delta\delta^{13}\text{C}_{\text{NP-EQ}_{\text{G.hex}}}$ are slightly positive during glacial maxima. Similar to the increased $\Delta\delta^{13}\text{C}_{\text{NP-EQ}_{\text{G.hex}}}$ from Bering Sea core U1342 during extreme glacials, a recent high-resolution $\delta^{13}\text{C}$ comparison between western Bering Sea (Shirshov Ridge) core SO201-2-101KL and ODP Site 1240 *G. hexagonus* over the past 60 ka [Max et al., under review, this thesis] indicates a close resemblance of sub-thermocline waters to North Pacific waters during MIS 2.

Rella et al. [2012] argue that the formation of GNPIW was initiated in the Bering Sea by the closure of the Bering Strait and an easternmost position of the Aleutian Low. This pooled relatively fresh water within the Bering Sea and fostered a strengthened pycnocline [Riethdorf et al., 2016]. The newly formed intermediate water with high oxygen content and low salinities was present in the subarctic Pacific from ~60 ka until the beginning of Termination I [Schlung et al., 2013]. Further support comes from a ϵ_{Nd} study indicating that intermediate waters from the Bering Sea were a principle component of GNPIW during MIS 2 and MIS 6 [Horikawa et al., 2010] and seems to be a reoccurring feature during the past 1.2 Ma [Knudson and Ravelo, 2015a]. The enhanced stratification prevented upwelling of nutrients from below and as a consequence, isolated the available nitrate at the surface [Knudson and Ravelo, 2015b; Riethdorf et al., 2016]. High nitrogen isotopes indicate an enhanced nutrient utilization in the Bering Sea during MIS 2 and MIS 6 [Galbraith et al., 2008; Brunelle et al., 2010; Knudson and Ravelo, 2015b; Riethdorf et al., 2016]. However, it was reported that productivity and export production remained low during glacial maxima [Kienast et al., 2004; Jaccard et al., 2005; Gebhardt et al., 2008; Brunelle et al., 2010; Kim et al., 2011]. The combined evidence for an increased GNPIW formation but reduced primary productivity in the subarctic Pacific and a decreased $\delta^{13}\text{C}$ difference between the Bering Sea core and EEP sub-thermocline argues for an enhanced nutrient-injection of GNPIW into equatorial sub-thermocline waters during peak glacials. This nutrient-injection was higher than today. Thereby it confirms a previous $\delta^{13}\text{C}$ compilation, which postulates increased North Pacific mid-depth circulation that expands southward and eastward between 700 – 2600 m water depth in the subarctic Pacific [Matsumoto et al., 2002a].

The penultimate glacial maximum (MIS 6) shows larger $\Delta\delta^{13}\text{C}_{\text{NP-EQ}_{\text{G.hex}}}$ values than MIS 2 (Figure 5.4), which suggests an even higher nutrient-contribution from northern-sourced waters into the equatorial upwelling waters. A model simulation investigates the extension of past glaciations and found colder MIS 6 conditions with an extensive Eurasian ice sheet compared to MIS 2 [Colleoni et al., 2016]. Furthermore, in the Sea of Okhotsk ice-rafted debris accumulation was 2 – 3 times higher due to extensive mountain glaciers during MIS 6 compared to the LGM [Nürnberg et al., 2011]. Together with the change from seasonal to still mobile perennial sea ice cover [Nürnberg et al., 2011], GNPIW formation could have been further intensified during MIS 6. As persistent stratification and nearly complete surface nutrient utilization prevailed during that time

[*Riethdorf et al.*, 2016], the nutrient-injection into equatorial sub-thermocline waters might have been enhanced and possibly explains the larger $\Delta\delta^{13}\text{C}_{\text{NPN-EQ}_{G,\text{hex}}}$ during MIS 6 compared to MIS 2.

An expanded GNPIW circulation could also explain the increased ventilation along the California margin during MIS 6 as well as MIS 3 and MIS 2 [*Stott et al.*, 2000]. Therefore, we compared ODP Site 1240 and EW9504-04 (32°17'N, 118°24'W, 1759 m water depth, 1400 sill depth) (Figure 5.1) [*Stott et al.*, 2000] to investigate possible $\delta^{13}\text{C}$ modifications along the flow path of GNPIW. The carbon isotope comparison between EW9504-04 and ODP Site 1240 ($\Delta\delta^{13}\text{C}_{\text{CCM-EQ}_{G,\text{hex}}}$) yields a similar pattern as $\Delta\delta^{13}\text{C}_{\text{NPN-EQ}_{G,\text{hex}}}$ with small differences during glacials and high differences during past interglacials due to very low $\delta^{13}\text{C}$ values at the Californian margin (Figure 5.4d). The amplitude of $\Delta\delta^{13}\text{C}_{\text{CCM-EQ}_{G,\text{hex}}}$ is less pronounced compared to the $\Delta\delta^{13}\text{C}_{\text{NPN-EQ}_{G,\text{hex}}}$ record, possibly because regional circumstances such as sill depths and local productivity along the California margin modify the $\delta^{13}\text{C}$ of EW9504-04 slightly [*Stott et al.*, 2000]. Nevertheless, these regional differences do not influence the general pattern, as $\delta^{13}\text{C}$ comparisons between $\delta^{13}\text{C}_{G,\text{hexagonus}}$ of ODP Site 1240 and benthic $\delta^{13}\text{C}$ records cores from additional sediment cores of the California margin (ODP Site 1012, *Andreasen et al.* [2000] and ODP Site 1014, *Hendy and Kennet* [2000], here termed CM_{add} , both not shown) indicate a very similar pattern as $\Delta\delta^{13}\text{C}_{\text{CCM-EQ}_{G,\text{hex}}}$ with higher $\Delta\delta^{13}\text{C}_{\text{CM}_{\text{add}}-\text{EQ}_{G,\text{hex}}}$ values during glacial maxima and lower $\Delta\delta^{13}\text{C}_{\text{CM}_{\text{add}}-\text{EQ}_{G,\text{hex}}}$ values during interglacials. It thereby supports an earlier Pacific carbon isotope study that found a relatively larger contribution of well-oxygenated (ventilated) waters between 1000 – 2600 m water depth originating in the North Pacific [*Duplessy et al.*, 1988]. A more recent stable isotope analyses off the Baja California margin by *Herguera et al.* [2010] concluded that the observed $\delta^{13}\text{C}$ -enriched intermediate waters are the result of a changed thermohaline circulation with a possibly enhanced GNPIW formation mode. Further south in the ETNP, a carbon isotope study by *Leduc et al.* [2010] proposed that GNPIW spreads at least till 8°N during the last glacial. Hence, it seems as if the enhanced ventilated GNPIW is progressively expanding southward, and thereby reaches the California margin and ETNP at the start of the glaciations. During glacial maxima, the volume of GNPIW expanded even further south reaching the equatorial sub-thermocline waters (Figure 5.5). Thereby, it possibly also changed the chemistry of the equatorial sub-thermocline waters, which is consistent with findings of *Loubere et al.* [2003, 2011], and *Max et al.* [under review, *this thesis*].

Our $\delta^{13}\text{C}$ comparisons together with previously published results show that large-scale reorganization in the formation area of GNPIW and SOIW took place during glacial stages that amplified during glacial maxima. In the western equatorial Pacific, these high latitude intermediate waters are incorporated into the equatorial current system. Thus, glacial/interglacial changes in this area affect the relative contribution of extra-tropical intermediate waters within the EqPIW as well. An idealized layer modeling shows that with the reduction of the Indonesian Throughflow during glacial conditions the proportion of GNPIW that was deflected into the tropical EqPIW increased [*McCreary and Lu*, 2001] and thus reaches the EEP sub-thermocline during glacial maxima. Fur-

thermore, under modern conditions the NECC, which in turn also feeds the EUC, is fed from both hemispheres (see *Chapter 5.1.2*). Only during the Northwest Monsoon, the SEC is prevented from injecting into the NECC, and thus, the NECC is only fed from the north [Tomczak and Godfrey, 2005]. A hydrogen isotope record together with regional modeling reconstructed a southward position of the mean Intertropical Convergence Zone (ITCZ) and an intensification of Northeast trade winds during the last glacial [Pahnke et al., 2007]. The glacial southward shift of the ITCZ is further verified by nitrogen isotopes and organic carbon records [Dubois and Kienast, 2011], biomarker analysis [Shaari et al., 2013], and by nanofossil assemblages [Staines-Urías et al., 2015]. The resulting stronger northeast trades might have reduced the northward penetration and contribution of SOIW to the NECC and possibly also the EqPIW. Thereby, it provides a possible scenario for our proposed relatively enhanced contribution of northern-sourced waters on the equatorial Pacific sub-thermocline during late MIS 2 and late MIS 6.

5.5.3 Deglacial and interglacial change in EEP nutrient-concentration

The $\delta^{13}\text{C}$ comparisons between high latitude and EEP upwelling waters yield rapid changes within the Termination I and II. The $\delta^{13}\text{C}$ difference between the Bering Sea and ODP Site 1240 increases towards modern values (Figure 5.4), which suggests decreasing nutrient-injections from northern-sourced intermediate waters into EqPIW. The GNPIW retreat is supported by the deposits of laminated sediments around the subarctic Pacific that indicates less well ventilated intermediate waters and the expansion of the oxygen minimum zone in the subarctic Pacific [Kuehn et al., 2014]. The increasing temperatures and the opening of the Bering Strait triggered a change in productivity [Riethdorf et al., 2016]. Low nitrogen isotopes indicate enhanced productivity that was explained by a change towards seasonal sea ice, decreased upper ocean stratification and subsequent enhanced nutrient supply to the euphotic zone by mixing and renewed riverine input [Gebhardt et al., 2008; Knudson and Ravelo, 2015b; Riethdorf et al., 2016]. Consequently, the increasing $\delta^{13}\text{C}$ difference between the Bering Sea and the EEP during warm periods suggests that northern-sourced intermediate water masses were depleted in nutrients during interglacials compared to glacials and more confined to the modern extent.

On the other hand, the both $\Delta\delta^{13}\text{C}_{\text{EQ}_{\text{G,hex}}\text{-SP}}$ records show increasing values from the glacial maxima towards the interglacials. This argues for an intensified southern-sourced nutrient-injection into the equatorial sub-thermocline. Silicon isotopes from the Southern Ocean indicate elevated $\text{Si}(\text{OH})_4$ concentrations at mode and intermediate depths in the SAZ [Rousseau et al., 2016]. The excess dissolved silicon is then transported equatorwards as described by the SALH [Hendry and Brzezinski, 2014]. Loubere et al. [2003, 2007] found that the re-establishment of deep EUC waters with a mainly southern-sourced water mass occurred roughly at 18 ka. This is in harmony with a stable isotope study from the EEP showing an increased inflow of SOIW at the onset of the terminations [Pena et al., 2008; 2013; Bova et al., 2015]. The intensified SOIW ventilation expanded further north into the ETNP, where $\delta^{13}\text{C}$ records and ϵ_{Nd} signatures show compa-

rable values to southern Ocean signatures within the deglaciation [Leduc *et al.*, 2010; Basak *et al.*, 2010].

5.6 Conclusions

This study investigates the varying influence of extra-tropical intermediate waters on EEP sub-thermocline. The carbon isotope comparisons indicate decreasing $\Delta\delta^{13}\text{C}$ ratios between the Equatorial sub-thermocline and the Southern Ocean records during peak glacials, which imply a diminishing relative nutrient influence from SOIW. On the other hand, the $\delta^{13}\text{C}$ comparisons between EEP sub-thermocline record and sediment cores within the pathway of GNPIW indicate minor $\delta^{13}\text{C}$ differences between the regions during peak glacials. This argues for enhanced GNPIW ventilation and subsequently relative enhanced nutrient contribution on equatorial sub-thermocline waters during late MIS 2 and late MIS 6.

The signal of relative increasing GNPIW influence on equatorial sub-thermocline would have large effects on biological productivity, as GNPIW is nutrient elevated compared to SOIW. Given that the modern EEP acts as one of the biggest CO_2 source on Earth today, past changes in the biological pump of the equatorial Pacific might have affected the balance between oceanic and atmospheric CO_2 concentrations. There is growing debate, whether the EEP turned into a sink for atmospheric CO_2 during at least the last glacial [Sanyal and Bijma, 1999; Martínez-Botí *et al.*, 2015]. The expansion of nutrient-rich GNPIW might be another piece of the puzzle to further understand atmospheric CO_2 variations during the Pleistocene and in particular during peak glacial periods.

Acknowledgments and Data

This research used samples provided by the Ocean Drilling Program (ODP). ODP is sponsored by the U.S. National Science Foundation (NSF) and participating countries under the management of Joint Oceanographic Institutions (JOI), Inc. We are grateful to L. Schönborn and G. Meyer for conducting stable isotope measurements at the AWI stable isotope lab. NR was funded by the German Ministry for Education and Research (BMBF – Bundesministerium für Bildung und Forschung) in the framework of the joint project Manihiki II (03G0225B). LM received funding through the Helmholtz Climate Initiative REKLIM (Regional climate change). The data of this study are available at PANGEA (URL: <http://www.pangaea.de>).

6. Conclusion and Outlook

6.1 Conclusion

The overall aim of this thesis was to investigate long-term variations in the upper ocean nutrient circulation in the Pacific Ocean. The emphasis of this work was the equatorial Pacific sub-thermocline and its relationship to increased intermediate water ventilation in the North Pacific. The assessment of precise regional foraminiferal ACDs is another important aspect of this thesis, as planktonic foraminifera generally serve as a tool to reconstruct past upper-ocean conditions. For this purpose, multiple different proxies were applied including the measurements of physical and chemical water properties, Mg/Ca ratios of planktonic foraminifera and benthic and planktonic $\delta^{18}\text{O}$ and $\delta^{13}\text{C}$ values, as well as the determination of foraminiferal abundances. The obtained results of this thesis together with relevant published records from the Pacific, archives profound outcomes concerning the raised research questions that given in *Chapter 1.5*.

The comparison between in-situ physical and chemical water mass properties with $\delta^{18}\text{O}_{\text{calcite}}$ values and Mg/Ca-derived temperatures measured on five living planktonic foraminifera species enabled species-specific ACDs and $\delta^{13}\text{C}$ -disequilibrium in the WPWP to be obtained (*Chapter 3*). It was shown that the relative order of *G. ruber* as the shallowest dweller, followed by *G. sacculifer*, *N. dutertrei*, *P. obliquiloculata* and *G. hexagonus* inhabiting increasingly greater depths, is similar to other ocean basins. However, the relatively deep SML in the WPWP during the period of sampling (reaching a maximum depth of ~130 m) resulted in the ACD of *G. ruber* and *G. sacculifer* of ~95 m and ~120 m respectively, which is deeper than in other ocean basins. As vital effects further affect symbiont-bearing species, a combined approach of foraminiferal abundances, local hydrography and determined ACDs provides the most reliable ACD reconstructions for these SML dwellers. At the top of and within the thermocline in the WPWP, both *N. dutertrei* and *P. obliquiloculata* calcify in water depths of ~140 m and ~160 m, respectively. We found that for the reconstruction of thermocline conditions, *P. obliquiloculata* seems to be most promising at the Manihiki Plateau. Most significantly, the ACD assessment reveals that *G. hexagonus* prefers to calcify in cooler, more oxygen-depleted and nutrient-rich sub-thermocline water masses at ~450 m. This species seems to have only negligible $\delta^{13}\text{C}$ -disequilibrium with ambient seawater and thus, *G. hexagonus* was found to be most suitable for reconstructing the long-term variability in extra-tropical nutrient injections into the equatorial current system.

Furthermore, GNPIW ventilation and the variable influence of northern-sourced versus southern-sourced water masses in the eastern tropical Pacific was reconstructed using the newly generated benthic foraminiferal $\delta^{13}\text{C}$ data from the Bering Sea and the new sub-thermocline $\delta^{13}\text{C}$ record from the EEP (*Chapter 4 and 5*). An increased formation of GNPIW was observed since the onset of MIS 3 by combining $\delta^{13}\text{C}$ records and ϵ_{Nd} evidence from the Bering Sea. The resemblance between our Bering Sea sediment core (SO201-2-101KL) and a previously published benthic $\delta^{13}\text{C}$ record from the Panama Basin (MD02-2529) suggests a southward expansion of GNPIW into the tropical North Pacific during glacial boundary conditions (*Chapter 4*). This finding is supported by a ϵ_{Nd} comparison between the Bering Sea and the eastern North Pacific, which indicates that the enhanced GNPIW ventilation during glacials reached Baja California. The southward penetration of GNPIW culminated early in MIS 2 (~29 ka). During that time $\delta^{13}\text{C}$ measured on deep-dwelling planktonic species *G. hexagonus* at ODP Site 1240 reveals remarkable similarities with SO201-2-201 KL. These similarities are accompanied by changes in marine productivity and nutrient utilization in the EEP. This likely suggests nutrient leakage from northern-sourced waters on equatorial Pacific sub-thermocline water masses during MIS 2.

So far, environmental changes within the EEP have only been correlated to SOIW due to the large contribution of southern-sourced water masses on EqPIW today. To investigate long-term changes spanning more than one glacial cycle, we compared the sub-thermocline $\delta^{13}\text{C}$ record of ODP Site 1240 to records from the Bering Sea (U1342), the eastern North Pacific (EW9504-04), the southwest Pacific (SO136-003/MD06-2990) and the southeast Pacific (PS75/059-2) (*Chapter 5*). The comparison of carbon isotope records indicates that $\delta^{13}\text{C}$ values between the North Pacific and the equatorial sub-thermocline are nearly identical during peak MIS 2 and late MIS 6. At the same time, the largest offset is recorded in the $\delta^{13}\text{C}$ values between EqPIW and SOIW. In agreement with the evidence for a reduced production and/or shallower penetration of SOIW and the enhanced North Pacific mid-depth circulation, the results of this thesis argue for repeated episodes of enhanced nutrient-injection of GNPIW coupled with diminished contribution from southern-sourced waters into the EqPIW during Pleistocene peak glacials.

6.2 Outlook

To ensure paleoceanographic reconstructions as precisely as possible, it is essential to accurately determine the ACD of each species. It has been proven that ACDs vary regionally, but also seasonally [e.g. *Kawahata et al*, 2002; *Steph et al.*, 2009]. The multinet study shown in *Chapter 3* presents for the first time foraminiferal ACDs from the south-eastern margin of the equatorial Pacific. It should be noted that this study was conducted during a single season at one location. For the western equatorial Pacific there exist no spatial ACD assessments, although chlorophyll data suggest a deeper chlorophyll maximum north and south of the equator. In addition, a one-year sediment trap analyses from the western equatorial Pacific highlights a seasonal difference in planktonic foraminifera abundance, which might be related to the varying strength of trade winds

and the associated nutrient concentrations [Kawahata *et al.*, 2002]. Consequently, for a more reliably spatial-refined ACD assessment and to prevent a seasonally biased interpretation of paleo-data, additional multinet studies distributed within the WPWP and the EEP are needed. This thesis demonstrates the suitable application of sub-thermocline dwelling *G. hexagonus* to trace varying nutrient concentrations in equatorial Pacific sub-thermocline waters. Marchant *et al.* [1998] showed that, at least in the Peru-Chile current, the abundance of *G. hexagonus* did not differ seasonally. However, studies of this species are scarce. Indeed, different ACDs have been reported from the Pacific Ocean and the Indian Ocean (Chapter 3.3.3.3) Hence, more detailed information concerning regional calcification depths in the WEP and EEP, seasonal variations in abundances, feeding and the reproduction cycle would aid the use of *G. hexagonus* as an archive for sub-thermocline water masses.

The climate phenomenon ENSO causes large variations of the SSTs, large changes in precipitation, and a change in the depth of the thermocline and the associated availability of nutrients. El Niño events occur with a periodicity of 3 – 8 years and a duration of ~6 months. This periodicity is typically too short to be resolved by most sedimentary records, especially at the Manihiki Plateau where sedimentation rates are low (1 – 3 cm/kyr) [Beiersdorf *et al.*, 1995; Radatz *et al.*, submitted (*abstract in the appendix*)]. Despite the difficulty in resolving such short time periods, it has often been discussed whether glacial climate prevailed in a more El Niño-like state [e.g. López-Otálvaro *et al.*, 2008; Li *et al.*, 2011; Sadekov *et al.*, 2013] or La Niña-like conditions [e.g. Beaufort *et al.*, 2001; Staines-Urías *et al.*, 2015]. These different climate modes could cause a shift in the ACD of especially SML- and thermocline-dwelling species. Consequently, ACD assessments during El Niño and La Niña events are needed to better constrain past glacial-interglacial oceanic and climate changes.

Our new downcore reconstructions indicate that past changes in North Pacific mid-depth circulation influenced the carbon signature of equatorial sub-thermocline water masses during peak glacial conditions. To record the long-term evolution of equatorial Pacific sub-thermocline waters, the $\delta^{13}\text{C}$ record of *G. hexagonus* was compared to the $\delta^{13}\text{C}$ record of Bering Sea sediment core U1342. The latter was measured on infaunal benthic *U. peregrina* that was corrected with a modern constant offset of +0.9 ‰ with respect to bottom water $\delta^{13}\text{C}_{\text{DIC}}$ [Duplessy *et al.*, 1984; Knudson and Ravelo, 2015a]. However, a number of studies have shown that this offset is highly variable on glacial-interglacial timescales [Pahnke and Zahn, 2005; McCave *et al.*, 2008; Ronge *et al.*, 2015], decreasing our confidence in the utility of *U. peregrina* as a tracer of past bottom water $\delta^{13}\text{C}_{\text{DIC}}$. This is particularly important as the contribution of Bering Sea Intermediate Water to GNPIW during glacial conditions, remains enigmatic [Tanaka and Takahashi, 2005; Horikawa *et al.*, 2010; Rella *et al.*, 2012; Max *et al.*, 2014; Matul *et al.*, 2015; Cook *et al.*, 2016]. Thus, it would be beneficial to compare a high-resolution record of epibenthic *Cibicidoides* from the Bering Sea and the Sea of Okhotsk, which covers more than one glacial-interglacial cycle, to equatorial intermediate waters. This would enable a more accurately determination of the specific North Pacific end-member signature and contribution to equatorial upwelling waters during glacials and

across the terminations. In addition, it would allow more accurate constraints to be placed on the timing of the switch from northern- to southern-sourced water masses feeding into the equatorial Pacific.

This thesis also revealed that GNPIW might have changed glacial equatorial nutrient availability by providing preformed nutrients to EqPIW, which we defined as the 'North Pacific Nutrient Leakage' hypothesis. This nutrient leakage from the north argues for a relaxation of the nutrient limitation in the EEP. To date, there is no consistent information regarding glacial equatorial productivity [Loubere *et al.*, 2003; Bradtmiller *et al.*, 2006; Pichevin *et al.*, 2009; Robinson *et al.*, 2009; Arellano-Torres *et al.*, 2011; Calvo *et al.*, 2011; Dubois *et al.*, 2011], but a north-south dichotomy in the primary productivity within the EEP during MIS 2 emerges [Bova, personal communication]. Whether this reflects atmospheric shifts in the position of the ITCZ and thus variations in upwelling, or variations in the contribution of nutrients from the different end-members, remains uncertain. To elucidate this matter, necessary information about utilization processes of major nutrients in the GNPIW formation region are needed. Recent studies from the Bering Sea hint to low glacial mass accumulation rates of biogenic opal and decreased glacial nitrate utilization [Schlung *et al.*, 2013; Knudson and Ravelo, 2015b]. However, information on other major nutrients such as silicon and iron are absent. As northern-sourced water inject ~70 % of the modern $\text{Si}(\text{OH})_4$ into equatorial upwelling waters [Sarmiento *et al.*, 2004], more information on glacial-interglacial variations in this input are required. For example, silicon isotopes in the formation region of GNPIW combined with published records from the Southern Ocean would possibly allow us to infer the sources of productivity changes at the equator during glacials.

Understanding the causes of productivity changes in the equatorial Pacific would enable scientists to make more accurate estimations about the role of the equatorial Pacific within the past global CO_2 budget. To date, there is no real consensus about the emission of CO_2 to the atmosphere during glacials. A boron isotope study from the EEP proposes that the glacial oceanic CO_2 emission was even larger than today [Sanyal and Bijma, 1999]. In contrast, a more recent boron isotope study from the same area calculated that the EEP turned from a carbon source towards a CO_2 sink in the last glacial [Martínez-Botí *et al.*, 2015]. Supporting evidence for an environmental change towards a glacial CO_2 sink comes from a diatom-bound carbon isotope calculation from the tropical western Pacific [Xiong *et al.*, 2013]. In summary, a more coherent understanding of past changes in the equatorial Pacific will enable us to more accurately infer potential future ocean dynamics in this climatically sensitive region, improving future global climate predictions.

Acknowledgement

First of all, I want to thank my supervisor Ralf Tiedemann for giving me the opportunity to do my PhD and supported me along the way. Also I want to thank Gerhard Bohrmann for reviewing this thesis and appreciate all the helpful comments from all the members of my thesis committee. Special thanks also to Isabel Cacho for giving me the opportunity to work at ODP Site 1240 and supporting me during my stay in Barcelona.

I am particularly grateful for everyone who has helped me along my way. My gratitude goes to Dirk Nürnberg and Lars Max for their support, constructive comments, discussions and reviews. And special thanks to all the co-authors for their great help and ideas during writing and editing.

I really appreciate also the technical help of Antje Mewes, Birgit Glückselig, Günter Meyer, Janette Voigt, Lisa Schönborn, Susanne Wiebe, Rita Fröhlking-Teichert and Ute Bock. Without your silent support it would have been impossible to do this work. Furthermore, great thanks goes to Michal Kucera and Barbara Donner for their guidance during foraminiferal identification and sample preparation. And many thanks to my office mate Jenny for language assistance.

Special thanks to Edith for her amazing support and coffee times. Without you I could not have imagined publishing the papers and doing this! Special thanks also for Sarah and Verena for your comments, open ears and fun times in and outside the office.

Muchas gracias a mis amigos Patri, Olia, Albert y Mercé. I really appreciate all your support with work, bureaucracy, Catalan language and great times in Barcelona. It's been amazing getting to know you.

Also special thanks to all other PhD students from the Marine Geology Department at AWI, and from all the different other AWI departments. It was great meeting so many others along the way. Furthermore, I thank the people from Urbino 2014 for the laughter, fun and experiences in and outside of science.

Additionally, I want to thank the members of the DokTeam and the graduate school POLMAR for their support and this great experience being a DokTeam member. It really pushed me forwards working together with you.

The most personal and special thanks for all the help and support during this exciting, challenging and demanding times goes to my family and my freak. I could not have done it without your open ear and your encouragement!

Data Handling

All data presented in this thesis will be stored electronically and will be available online in the PANGAEA-database at www.pangaea.de.

Abstract

The internal development of the tropical West Pacific Warm Pool and its interaction with other ocean regions on geological timescales is only poorly constrained. Based on two newly recovered sediment cores from the southeastern margin of the West Pacific Warm Pool (northern and southern Manihiki Plateau), we provide new aspects on the dynamically interacting ocean circulation at surface, subsurface, thermocline, and deep thermocline levels during the Pleistocene (~2.5 – 0.5 Ma). Notably, the variability of thermocline and deep thermocline (~150– 400 m water depth) foraminiferal Mg/Ca-based temperatures with up to ~6°C amplitude variations exceeds those at shallower depths (down to ~120 m) with only ~2 – 3°C temperature variations. A major gradual reorganization of the West Pacific Warm Pool oceanography occurred during the transitional time period of ~1.7 – 1.35 Ma. Prior to ~1.7 Ma, pronounced meridional and latitudinal gradients in sea-surface to subsurface ocean properties point to the sustained eastward displacement of the West Pacific Warm Pool, with the South Pacific Convergence Zone being shifted further northeastward across Manihiki Plateau. Simultaneously, the low amplitude variations of thermocline and deep thermocline temperatures refer to an overall deep and stable thermocline. Our data further suggest that pronounced upper ocean temperature gradients between the Eastern and western equatorial Pacific were established by several hundred thousand years earlier than previously suspected, contradicting notions on permanent El Niño-like conditions until

~1.7 Ma. The meridional and zonal gradients in sea-surface and subsurface ocean properties diminished within the West Pacific Warm Pool, pointing to close-to-present-day temperature conditions particularly between ~1.7 – 1.35 Ma and ~0.9 – 0.75 Ma, and the more southward position of the warm South Pacific Convergence Zone at ~1.35 – 0.9 Ma and ~0.75 – 0.5 Ma. Synchronous to the changes in the upper ocean, the deeper water masses experienced high amplitude variations in temperature, most prominently since ~1.5 Ma. This and the dynamically changing thermocline conditions most likely occurred in response to the impact of southern-sourced mode waters, which developed coincidentally with the emergence of the East Pacific Cold Tongue and high latitude sea-surface cooling.

Abstract

To reconstruct the still poorly understood thermocline fluctuations in the western tropical Indian Ocean, a sediment core located off Tanzania (GeoB12610-2; 04°49.00'S, 39°25.42'E, 399 m water depth) covering the last 35 ka was analysed. Mg/Ca-derived temperatures from the planktonic foraminifera *Globigerinoides ruber* (white) and *Neogloboquadrina dutertrei* indicate that the last glacial was ~2.5°C colder in the surface waters and ~3.5°C colder in the thermocline compared with the present day. The depth of the thermocline and thus the stratification of the water column were shallower during glacial periods and deepened during the deglaciation and Holocene. The increased inflow of Southern Ocean Intermediate Waters via 'ocean tunnels' appears to cool the thermocline from below, leading to a similarity between the thermocline record of GeoB12610-2 with the Antarctic EDML temperature curve during the glacial. With rising sea level and the corresponding greater inflow of Red Sea Waters and Indonesian Intermediate Waters, the proportion of Southern Ocean Intermediate Water within the South Equatorial Current is reduced and, by Holocene time, the correlation to Antarctica is barely traceable. Comparison with the eastern Indian Ocean reveals that the thermocline depth reverses from the last glacial to present.
