(Received 20 January 2001; accepted 10 October 2001)

Sequence variation among 22 isolates representing a global distribution of the prymnesiophyte genus Phaeocystis has been compared using nuclear-encoded 18S rRNA genes and two non-coding regions: the ribosomal DNA internal transcribed spacer 1 (ITS1) separating the 18S rRNA and 5.8S rRNA genes and the plastid ribulose-1,5-bisphosphate carboxylase/oxygenase (RUBISCO) spacer flanked by short stretches of the adjacent large and small subunits (rbcL and rbcS). 18S rRNA can only resolve major species complexes. The analysis suggests that an undescribed unicellular Phaeocystis sp. (isolate PLY 559) is a sister taxon to the Mediterranean unicellular Phaeocystis jahnii; this clade branched prior to the divergence of all other Phaeocystis species, including the colonial ones. Little divergence was seen among the multiple isolates sequenced from each colonial species complex. RUBISCO spacer regions are even more highly conserved among closely related colonial Phaeocystis species and are identical in Phaeocystis antarctica, Phaeocystis pouchetii and two warm-temperate strains of *Phaeocystis globosa*, with a single base substitution in two cold-temperate strains of *P. globosa*. The RUBISCO spacer sequences from two predominantly unicellular *Phaeocystis* isolates from the Mediterranean Sea and PLY 559 were clearly different from other Phaeocystis strains. In contrast, ITS1 exhibited substantial inter- and intraspecific sequence divergence and showed more resolution among the taxa. Distinctly different copies of the ITS1 region were found in P. globosa, even among cloned DNA from a single strain, suggesting that it is a species complex and making this region unsuitable for phylogenetic analysis in this species. However, among nine P. antarctica strains, four ITS1 haplotypes could be separated. Using the branching order in the ITS1 tree we have attempted to trace the biogeographic history of the dispersal of strains in Antarctic coastal waters.

Key words: biogeography, ITS1, Phaeocystis, phylogeny, Prymnesiophyceae, RUBISCO spacer, 18S rRNA

Introduction

Species separation in the ecologically important, cosmopolitan phytoplankton genus Phaeocystis is difficult using morphological features seen with light microscopy. The morphological features that can be used to separate the species can be found in Davidson & Marchant (1992) and in Zingone et al. (1999) and have been summarized in Table 1 here. The genus itself is easy to recognize if specimens are in the large gelatinous colony stage but *Phaeocystis* has a complex polymorphic life cycle with both colonial and single-cell stages (Kornmann, 1955; Rousseau et al., 1994). Older colonial stages are more difficult to identify to species because the distinct colony morphology begins to break down. The single-cell stage is even more difficult to determine to either the genus or species level without

Correspondence to: L. K. Medlin. e-mail: lmedlin@awi-bremer-haven.de

electron microscopy. It still not clear how the many documented life stage forms in Phaeocystis interrelate with one another and the life cycle in Rousseau et al. (1994) is hypothetical. Only a few electron microscopic characters of the flagellate cell stage have been considered stable and are recommended for use in identifying Phaeocystis species unequivocally (Sournia, 1988). Recently, the species status of three colonial *Phaeocystis* taxa was corroborated by sequence variation in their nuclearencoded 18S rRNA gene (Medlin et al., 1994), by physiological differences (Baumann et al., 1994) and, for two of the three colonial species, by differences in genome size (Vaulot et al., 1994). Furthermore, two new unicellular Phaeocystis species from the Mediterranean Sea have been recognized by sequence variation in the 18S rRNA gene (Zingone et al., 1999), by light and electron microscopic features (Zingone et al., 1999) and, for at least one of them, by genome size (Vaulot et al., 1994; Table 1).

Species	P. globosa	P. pouchetii	P. antarctica	P. cordata	P. jahnii
Dominant morphology	Spherical colony	Cloud-like colony	Spherical colony	Unicellular	Unicellular, rarely colonial
Maximum size	8–9 mm	1·5-2 mm	9 mm	$3.2 \times 3.8 \ \mu m$	$3.5 \times 5 \mu \mathrm{m}$
Mucilage in colony	Solid	Delicate	Solid	No colonies seen	Delicate, irregular, and loose aggregat
Distribution	Warm to cold-temperate	Arctic	Antarctic	Mediterranean	Mediterranean
DNA content	Group $1 = 32-35$ pg cell ⁻¹	31-36 crbc units ^{<i>a</i>} cell ⁻¹	$35-37 \text{ pg cell}^{-1}$	24 pg cell^{-1}	n.d.
	Group $2 = 38 \text{ pg cell}^{-1}$				
	Group $3 = 42-44 \text{ pg cell}^{-1}$				
Scale size: large	0·19–0·18 µm	$0.25-0.24 \ \mu m$	$0.25-0.24 \ \mu m$	$0.27 - 0.21 \ \mu m$	$0.35-0.28 \ \mu m$
Scale size: small	$0.13-0.10 \ \mu m$	$0.19-0.15 \ \mu m^b$	n.d.	$0.19-0.14 \ \mu m$	$0.18-0.14 \mu m$
Flagellar length	$10-15 \ \mu m$	8 µm	$10-12 \ \mu m$	Unequal: 8·5–12; 5·5–6·50 µm	Unequal: 5·5–7·5; 4·5–60 µm

Table 1. Summary of salient morphological features and genome sizes of *Phaeocystis* species investigated in this study, extracted from Davidson & Marchant (1992), Vaulot *et al.* (1994

In the past decade sequencing of the nuclearencoded ribosomal RNA (rRNA) genes and plastidencoded ribulose-1,5-bisphosphate carboxylase/ oxygenase (RUBISCO) large and small subunit genes have been successfully used to identify microorganisms and to infer phylogenetic relationships among taxa (Woese, 1987; Douglas & Durnford, 1989; Huss & Sogin, 1990; Fujiwara et al., 1993; Leipe et al., 1994; Birgitta et al., 1998; Daugbjerg & Andersen, 1997; Sogin & Silbermann, 1998). However, these coding regions are normally used to distinguish between higher taxa and reach their limitation at the species level (Hillis & Moritz, 1990). Faster-evolving DNA regions, such as noncoding spacer regions, are therefore needed to resolve closely related or recently evolved species or to study species at the population level.

In land plants and green algae, only the large subunit gene of RUBISCO is plastid-encoded; the small subunit gene has been transferred to the nucleus (Reith & Cattolico, 1986). However, genes for both the large and small subunits of RUBISCO are plastid-encoded in all chlorophyll-c-containing algae (except dinoflagellates) and in the rhodophytes and are separated by a short spacer region (Reith & Cattolico, 1986). RUBISCO spacer sequences have been reported from cryptophytes (Douglas et al., 1990), chloromonads (Boczar et al., 1989), prymnesiophytes (Fujiwara et al., 1993), phaeophyceans (Siemer et al., 1998), diatoms (Chesnick et al., 1996), pelagophytes (Bailey & Andersen, 1999) and rhodophytes (Muller et al., 1998). These spacer regions are relatively small in size (38–204 bp) and have been found to be highly conserved at the population and species level in most algal groups. A relatively large RUBISCO spacer (545 bp) was found, however, in the cyanobacterium Anabaena 7120 (Curtis & Haselkorn, 1983).

The rDNA internal transcribed spacer regions (ITS1 and ITS2) separate three ribosomal genes in the rDNA cistron of eukaryotes. Although there is little agreement about the biological function of the internal transcribed spacers, growing evidence indicates that these highly variable regions between the ribosomal genes play an important role in ribosome processing (van der Sande et al., 1992). ITS regions also evolve at a fast rate. For example, 0.8-2.0%base changes per Mya has been calculated for the chlorophyte Cladophora albida clade (Bakker et al., 1995). With such high base substitution rates and well-documented length variation in ITS regions, it is possible to resolve differences among closely related species or different populations within species (e.g. Lee & Taylor, 1991; Pleyte et al., 1992; Wesson et al., 1993; Schlötterer et al., 1994; Vogeler & DeSalle, 1994; Edvardsen & Medlin, 1998; Alice & Campbell, 1999; Booten et al., 1999). The use of ITS sequences for phylogenetic and biogeographic studies in marine algae is increasing, e.g. in marine and freshwater green algae (Bakker *et al.*, 1992, 1995; Kooistra *et al.*, 1992, 1993; van Oppen *et al.*, 1993; Coleman *et al.*, 1994; Pillmann *et al.*, 1997; Blomster *et al.*, 1998; Coat *et al.*, 1998; Gonzales *et al.*, 1998; Schagerl *et al.*, 1999), brown algae (van Oppen *et al.*, 1993; Peters *et al.*, 1997, Stache-Crain *et al.*, 1997; Siemer *et al.*, 1998), diatoms (Zechman *et al.*, 1994), dinoflagellates (Adachi *et al.*, 1997) and red algae (Steane *et al.*, 1991; Goff *et al.*, 1994; Vis & Sheath, 1997; Wattier *et al.*, 1997).

Differences in DNA content in 14 strains of Phaeocystis globosa as measured by flow cytometry (Vaulot et al., 1994) suggested that at least one colonial form, P. globosa, could contain multiple cryptic species. Vaulot et al. (1994; D. Vaulot, personal communication) detected at least three groups within *P. globosa*, which all differed from *P*. antarctica on the basis of their DNA content (Table 1). Sequence data from 18S rRNA genes of Phaeo*cystis* have been used to reconstruct the phylogeny and biogeographical history of its major, bloomforming and most commonly recorded species (Medlin et al., 1994; Lange, 1997; Zingone et al., 1999). However, variation in the 18S rRNA gene between P. globosa and P. pouchetii and among strains of P. antarctica was minor and ranged from 0 to 5 nucleotides (Medlin et al., 1994; Lange, 1997), making the resolution of closely related or recently evolved cryptic Phaeocystis species using these coding regions difficult.

Consequently, we sequenced 18S rRNA from additional strains of *P. globosa* and the RUBISCO spacer and the ITS1 spacer region of the ribosomal cistron from many *Phaeocystis* species to reconstruct the phylogenetic history of closely related *Phaeocystis* species/strains among the colonial species and to obtain an insight into the biogeographic history of *P. antarctica* and the separation of ancestral populations into two polar species, *P. antarctica* and *P. pouchetii*, using an analysis of both nuclear and plastid genomes.

Materials and methods

Cultures

Phaeocystis strains and other algae used in this study are listed in Table 2. Isolates were grown in K-medium (Keller *et al.*, 1987) or in an enriched seawater medium with major nutrients diluted by half or 50 times (von Stosch & Drebes, 1964) under a light/dark cycle suitable for growth at 0 °C, 10 °C and 15 °C (4:20, 12:12, 14: 10, respectively). We included multiple representatives of three colonial species, *P. globosa*, *P. antarctica* and *P. pouchetii*, and the only available cultures of three predominantly unicellular species, *P. cordata*, *P. jahnii* and *Phaeocystis* sp. (PLY 559). *Phaeocystis scrobiculata* Moestrup, known only from the flagellated stage in field

material (Zingone *et al.*, 1999), is the only recognized species not included in our analysis.

Isolation of DNA

Cultures were harvested during logarithmic growth, frozen in liquid nitrogen until needed or used directly for DNA extraction. Total nucleic acids were obtained using a 3% CTAB (hexadecyltrimethylammonium bromide) procedure (Doyle & Doyle, 1990). Other extractions were performed by resuspending the cells in extraction buffer (100 mM Tris, pH 8·5, 100 mM NaCl, 50 mM EDTA) before total nucleic acids were extracted by vortexing the cells in the presence of 2% SDS and Tris-buffered phenol/chloroform/isoamyl alcohol (50:48:2 v/v/v). The supernatant was extracted twice with phenol/ chloroform/isoamyl alcohol and once with chloroform/ isoamyl alcohol (48:2 v/v) prior to ethanol precipitation.

Amplification

Total nucleic acid preparations were used as templates for the amplification of the 18S rRNA gene and the ITS1 and RUBISCO spacers, except in a few cases where an entire Phaeocystis colony was used as template directly in the PCR reaction. The 18S rRNA genes were amplified following Chesnick et al. (1997). The ITS1 regions were amplified using a forward primer near the 3' end of the 18S rRNA gene of Phaeocystis (5' GCCGGACGCGAC-GCTCC 3', position 1705–1719) and a reverse primer that matched a conserved region at the beginning of the 5.8S rRNA gene (5' GCTACGTTCTTCATCGATGC 3'). RUBISCO spacer regions were amplified using primers complementary to conserved regions within the large and small RUBISCO subunits (Maggs et al., 1992). One of the two primers used in each amplification was biotin-labelled prior to its synthesis. Each 100 μ l PCR reaction contained 100 ng total nucleic acids and a PCR reaction mixture as described in Medlin et al. (1988). To amplify the ITS1 region of *Phaeocystis* it was essential to add 10 μ l of 50 % acetamide (Sigma) to the PCR reaction. The amplifications of the ITS1 region were performed in a Perkin-Elmer-Cetus thermocycler with an initial denaturation step of 95 °C for 6 min, after which the Taq polymerase was added as the heating block cooled to 60 °C, followed by 29 cycles of 72 °C for 4 min, 94 °C for 2 min, 45 °C for 2 min and a final extension step at 72 °C for 9 min.

For the Chinese isolate of *P. globosa*, purified gene products were ligated into the pUC18 vector following the manufacturer's instructions (Gene Company). A highly degenerate primer Phaeo LH₂ (5' CGGAAGG-ATCATTACCGGTAT 3') and D1a were used for clone selection. Several clones of each isolate were sequenced. The amplifications of RUBISCO spacer regions were performed with an initial denaturation step of 92 °C for 3 min, after which the *Taq* polymerase was added as the heating block cooled to 60 °C, followed by 29 cycles of 72 °C for 1 min, 94 °C for 45 s, 40 °C for 1 min and a final extension step of 72 °C for 5 min. Not all species could be amplified successfully for both spacer regions.

Sequence analysis

Single-stranded DNA was obtained by binding amplification products onto streptavidin-coated magnetic M-280

M. Lange et al.

^{*a*} Used for RUBISCO spacer sequencing. ^{*b*} Used for ITS sequencing. ^{*c*} Provasoli-Guillard Culture Center for Marine Phytoplankton, Bigelow Laboratory for Ocean Sciences, West Boothbay Harbor, Maine, USA. ^{*d*} Culture no longer available. ^{*e*} Phymouth Culture Collection, Phymouth Marine Laboratory, Phymouth, UK. ^{*f*} University of Bergen, Norway. ^{*g*} Université Pierre et Marie Curie, Station Biologique, Roscoff, France. ^{*h*} CSIRO Division of Fisheries, Hobart, Tasmania, Australia. ^{*i*} Stazione Zoologica Anton Dohrn, Naples, Italy.

Dyna-beads, following a slightly modified protocol of DYNAL (Oslo, Norway). Thirty microlitres of beads were washed with 200 μ l of binding buffer (10 mM Tris

HCl, pH 7.5, 1 mM EDTA, 2.0 M NaCl); all liquid was removed by magnetic separation. Beads were resuspended in 40 μ l binding buffer plus 90 μ l of the PCR

reaction solution containing the amplification products, followed by a gentle shaking of the solution for 30 min at room temperature. The beads were washed twice with 200 μ l of binding buffer, then all liquid removed and the beads resuspended in 20 μ l freshly prepared 0·1 N NaOH for 10 min at room temperature. Liquid was removed and stored on ice and an additional denaturation step with 100 μ l 0·1 N NaOH was performed followed by washing the beads three times with 200 l sterile water. Beads were finally resuspended in 11 μ l sterile water and used directly as template for sequencing. In some cases, DNA from the first denaturation step was precipitated with 500 μ l icecold 100% ethanol, kept for at least 1 h at -70 °C and spun in a microcentrifuge for 30 min at 13000 g at 4 °C. DNA was resuspended in 10 μ l sterile water and used directly for sequencing.

The 18S rRNA coding regions and ITS1 and RUBISCO spacer regions were sequenced using the dideoxynucleotide chain-termination sequencing method (Sanger *et al.*, 1977) with the T7-Sequencing Kit (Pharmacia) and the same primers as in the amplification reactions plus internal primers for the 18S rRNA gene (Elwood *et al.*, 1985). Primer annealing was performed by heating samples at 60 °C for 10 min and subsequently allowing them to cool at room temperature for 10 min. Sequencing reactions were run as described in Medlin *et al.* (1994).

All sequences were aligned manually using the Olsen sequence editor (Larsen et al., 1993). Both the RUBISCO and the ITS1 data sets were submitted to CLUSTAL-W for alignment and then corrected by eye. The 18S rRNA sequences were manually aligned to an algal database originating from the Ribosomal Database Project, which contains over 500 published and unpublished chlorophyll a+c algae, using maximum primary and secondary structural similarity. A final data set of 37 species/strains and 1764 nucleotides was used for phylogenetic analyses with the Class Pavlovophyceae as outgroup for the 18S rRNA gene. A recent analysis of all available prymnesiophyte 18S rRNA sequences has shown that the Class Pavlovophyceae is the sister group to the Class Prymnesiophyceae and is thus an appropriate outgroup for the Class Prymnesiophyceae (Edvardsen et al., 2000). The Phaeocystales are members of the Class Prymnesiophyceae (Edvardsen et al., 2000). RUBISCO spacer sequences from 12 Phaeocystis species/strains and one diatom contaminant from Phaeocystis sp. P197 were aligned with RUBISCO spacer sequences from other prymnesiophytes (Fujiwara et al., 1993; Barker, 1996), diatoms (Hwang & Tabita, 1991; Chesnick et al., 1996), phaeophyceans (Valentin & Zetsche, 1990) and rhodophytes (Destombe & Douglas, 1991), which were used as the outgroup for the RUBISCO spacer analysis. ITS1 spacer regions were aligned only within the genus *Phaeocystis*, using relationships inferred from the 18S rRNA data set to determine the appropriate outgroup. For the ITS analysis, two different data sets were used. The first data set analysed all available sequences and the bases marked as weighting mask 1 in Fig. 5. The second data set used only the polar species and the base positions marked as weighting mask 2 in Fig. 5. Within the polar data set more positions could be used for the analysis because more bases were considered to be unambiguously aligned.

Maximum likelihood analyses for the 18S rRNA gene and the RUBISCO spacer were performed using the fastDNAml program (v. 1.0) (Larsen et al., 1993, using the Felsenstein model). The ITS data set was analysed using the Modeltest program to determine the optimal evolution model for this data set from 40 available models (Posada & Crandall, 1998). This test found that the Felsenstein 1981 model of evolution best fitted the ITS data set in which all Phaeocystis sequences were included, whereas the Tamura and Nei model of evolution best fitted the second data set with only the polar strains. Both models allowed for a gamma distribution of the data. Options, empirically determined from the Modeltest program, were entered into the distance and maximum likelihood analyses settings in PAUP* v.4.0 (Swofford, 1999) where appropriate and used to run the bootstrap analyses. Maximum parsimony analyses were implemented with the PAUP* v.4.0 computer program (Swofford, 1999) using a re-scaled consistency index to weight the data. Introduced gaps were treated as missing data; informative characters were treated as multistate unordered. All trees were obtained using the treebisection-reconnection (TBR) branch swapping option in a heuristic search with random taxon addition. Distance analyses for the 18S rRNA gene and the RUBISCO spacer were performed using PHYLIP (Felsenstein, 1993), whereas the distance options in PAUP were used for the ITS analysis because we incorporated settings from the Modeltest program where appropriate. Dissimilarity values (Fitch & Margoliash, 1967), based on pair-wise comparisons of sequences, were transformed into distances using the Kimura two-parameter-models (Kimura, 1980). Distance matrices were converted into trees using the neighbor-joining method (Felsenstein, 1993). Stability of monophyletic groups in maximum parsimony and distance trees was estimated with a bootstrap analysis (500 replicates) (Felsenstein, 1985) and in a maximum likelihood analysis with 100 replicates.

Results

18S rRNA sequences

Fig. 1 shows the phylogenetic relationships among all available strains of Phaeocystis. The colonial species/strains fall into one clade (clade 2) that is sister taxon to the new unicellular species Phaeocystis cordata, which does not form colonies (Zingone et al., 1999). Together, these taxa are sister to another clade (clade 1) consisting of two other Phaeocystis strains, one of which is unicellular and undescribed (PLY 559) and the other of which, P. jahnii, can occasionally form loosely aggregated colonies (Zingone et al., 1999). The true colonial forms belong to three species: P. globosa, P. antarctica and P. pouchetii. No haptophytes in the other sister clades are colony formers: the formation of colonies is unique to *Phaeocystis* and is a derived condition. A thicker line on the tree (Fig. 1) indicates the warm temperature preference of some Phaeocystis spp.

Variation in the 18S rRNA gene occurs within and between each cluster of strains of a single

Fig. 1. Maximum likelihood phylogeny (fastDNAml) of 17 *Phaeocystis* species/strains and other prymnesiophytes inferred from 18S rRNA. The Class Pavlovophyceae was used as outgroup. Numbers placed to the left of the nodes are bootstrap values based on a neighbor-joining analysis (PHYLIP) and maximum parsimony analysis (PAUP, tree length = 167, CI = 0.952, RI = 0.956). Bootstrap values are placed on the nodes that are identical and recovered in all three analyses. Scale bar corresponds to 2 base changes per 100 nucleotides. Lines leading to warm-water taxa in the genus *Phaeocystis* are in enlarged font.

species. A bootstrap value of greater than 70 indicates that there is a probability of 95% that the clade is real (Hillus & Bull, 1993). The base positions separating one species cluster from another are consistent and unique within and between each species cluster and thus, each species cluster is supported by moderate to strong bootstrap support. There is little variation among the strains of each true colonial species (0–5 bases).

RUBISCO spacer

The spacer region separating the RUBISCO large and small subunits is 54 nucleotides in length in the three colonial species and is in the range reported in the literature from other algae (Destombe & Douglas, 1991; Fujiwara *et al.*, 1993; Goff *et al.*, 1994). A possible ribosome binding sequence (5' AGGAG 3') (Shine & Dalgarno, 1974) upstream of the initiation codon of the small subunit gene has been identified (Fig. 2). Similar regions have been found in all RUBISCO spacers investigated (see Bailey & Andersen, 1999).

The RUBISCO spacer in the colonial strains of *P. globosa, P. antarctica* and *P. pouchetii* was identical (Fig. 2). Only one base substitution was found in two cold-temperate strains of *P. globosa*. In contrast, the RUBISCO spacer of *P. cordata, P. jahnii* and the undescribed *Phaeocystis* species strain PLY 559 ranged from 59 to 79 nucleotides in length and differed from the other colonial *Phaeocystis* species by containing two insertions near the 5' end and multiple base substitutions (Fig. 2).

A clearly different RUBISCO sequence was obtained from one strain of *Phaeocystis* (P197) (Fig. 2), in repeated amplifications of this region from a single, well-washed *Phaeocystis* colony. Comparisons with other RUBISCO spacer sequences (Fig. 3) indicate the likelihood that we have amplified a diatom contaminant, which we believe resides inside the *Phaeocystis* colony. The RUBISCO spacer sequence from this isolate (Fig. 2) is basal to the known diatoms in our maximum likelihood tree (the diatom endosymbiont from *Peridinium foli*-

Fig. 2. Alignment of the RUBISCO spacer from the prymnesiophytes *Phaeocystis globosa* (strains SK 35, P 162, PCC 540, NIOZ 1), *P. antarctica* (strains SK 20, SK 22, CCMP 1374), *P. pouchetii* (strains SK 34, P 360), *P. cordata, P. jahnii, Phaeocystis* sp. PLY 559, *Pleurochrysis carterae* and *Emiliania huxleyi*, the phaeophycean *Ectocarpus siliculosus*, the diatoms *Cylindrotheca* sp., *Odontella sinensis*, the *Peridinium foliaceum* symbiont, a suspected diatom contaminant in the *Phaeocystis* P197 and the rhodophyte *Gracilaria gracilis* as outgroup. Base substitutions and insertions among *Phaeocystis* species are in bold. Shine–Dalgarno sequence near the 3' end of the RUBISCO spacer is underlined. Arrows indicate synapomorphies for cold-water *Phaeocystis* clade (position 221, position 242, position 268). All positions were used for these phylogenetic analyses. RUBISCO spacer is shown in capital letters, whereas flanking coding regions are in lower case.

Fig. 3. Maximum likelihood tree inferred from RUBISCO spacer sequences and a small part of the small subunit RUBISCO gene from *Phaeocystis globosa* (strains PCC 540, NIOZ 1), Phaeocystis cordata, Phaeocystis jahnii, Phaeocystis sp. PLY 559, Pleurochrysis carterae, Emiliania huxleyi, Ectocarpus siliculosus, Cylindrotheca sp., Odontella sinensis, the Peridinium foliaceum symbiont, a suspected diatom contaminant from Phaeocystis P197 and the rhodophyte Gracilaria gracilis as outgroup. The RUBISCO spacer sequences from *P. globosa* (strains SK 35, P 162, NIOZ 1), P. antarctica (strains SK 20, SK 22, CCMP 1374) and P. pouchetii (strains SK 34, P 360) are identical to that of P. globosa strain PCC 540 and were not included in the analyses. Bootstrap values are placed at the nodes from a maximum likelihood analysis (100 replicates), a neighbor-joining analysis (500 replicates) and a maximum parsimony analysis (500 replicates). Scale bar corresponds to 5 changes per 100 nucleotide positions.

aceum (Chesnick et al., 1996), Odontella sinensis and *Cylindrotheca* sp.) and is most closely related to that of the centric diatom Odontella (Figs 2, 3). In the maximum parsimony and neighbor-joining analyses all the diatoms fall into one clade and the contaminant is at the base of the clade (data not shown).

Quite unexpectedly, 105 nucleotides of the 5' end of the *rbc*S gene showed more variation among our isolates. As expected, many base substitutions were found in the unicellular Phaeocystis strains compared with the colonial *Phaeocystis* species/strains, which correlated well with morphological features (Zingone et al., 1999), 18S rDNA sequence data and flow cytometric measurements of genome size (Vaulot et al., 1994; Table 1). Also three informative sites in the 5' end of the rbcS gene were found that could be used to separate the colonial Phaeocystis species (Fig. 2). One site (position 221) separates the Phaeocystis warm-water species complex from Phaeocystis cold-water species complex, whereas position 242 separates P. antarctica strain SK 22 and P. pouchetii strains SK 34 and P360 from the remaining Antarctic Phaeocystis strains (SK 20 and CCMP 1374). Position 258 separates P. antarctica SK 20 and CCMP 1374 from the remaining coldwater species. P. antarctica strain SK 22 was isolated on the western side of Bouvet Island within the Antarctic Circumpolar Current (ACC) south of the Polar Front (Fig. 4, location 6).

The relationships among our taxa using the RUBISCO spacer are shown in Fig. 3. The relationships recovered are similar to those found in the 18S rRNA tree (Fig. 1), except that all colonial forms are identical (represented in the tree by P. globosa strain NIOZ) except for the single base substitution in two cold-temperate forms of P. globosa (represented in the tree by P. globosa strain PLY 540). The unicellular forms of *Phaeocystis* diverge before the colonial forms, as in the 18S rRNA tree.

ITS1

ITS1 regions from nine P. antarctica strains collected from different locations around Antarctica (Fig. 4, Table 2), one P. pouchetii strain from the Greenland Sea, five temperate/tropical strains of *P*. globosa and one of the unicellular species P. cordata were sequenced. In addition, we obtained, from GenBank, multiple ITS1 sequences from three P. globosa strains from China, Thailand and the Gulf of Mexico and an additional sequence of ITS1 from our Greenland strain of P. pouchetii (Table 2). These sequences were obtained from clone libraries. Boundaries of coding and non-coding regions were determined by comparison with published 18S rRNA genes of Phaeocystis (Medlin et al., 1994) and the 5.8S rRNA gene of the chlorophyte Cladophora albida (Bakker et al., 1992). ITS1 ranged in size from 259 to 273 nucleotides for P. antarctica, from 279 to 301 nucleotides for P. globosa, and was 256 bp in *P. cordata* (Table 3, Fig. 5). The 3' end of ITS1 from the directly sequenced PCR products of P. pouchetii was highly variable and could not be reliably aligned. Thus, the total size of the ITS1 region from this species was not determined. Nevertheless, many base substitutions and several deletion/insertion events were found within ITS1, clearly separating P. antarctica, P. pouchetii and P. globosa from one another and from *P. cordata* (Fig. 5, Table 3).

Fig. 4. (*A*) Locations of the strains of *P. antarctica* used in this study. Temperature isotherms at 100 m depth are shown on the map to indicate the position of the ACC (indicated on the temperature key) encircling the Antarctic (redrawn from plate 12 in Olbers *et al.*, 1962). The location of different clades is indicated by the different patterns in the large circles and correspond to those clades in Fig. 4*B*; numbers indicate the strains for which the ITS1 spacer region was determined (Table 2). Prydz Bay locations in E. Antarctica are slightly displaced for visual clarity (see Table 2 for precise location). (*B*) Maximum likelihood tree inferred from ITS1 sequences from *P. antarctica* (strains SK 20, SK 22, SK 23, CCMP 1374, DE2, T9-1, D4-5, A1-3 and T4-2) with *P. pouchetii* (SK 34 and clone 3) as outgroup. Only sequence positions marked in the weighting mask 2 (Fig. 5) were used for this phylogenetic analysis. Bootstrap values are placed at the nodes from a maximum likelihood analysis (100 replicates) a neighbor-joining analysis (500 replicates) and a maximum parsimony analysis (500 replicates) Scale bar corresponds to 2 changes per 100 nucleotide positions. The patterned circles beside the strains refer to the haplotype designation in our analysis; for locations of the strains see Fig. 4*A* and Table 2.

Fig. 5. Alignment of ITS1 sequences from *P. globosa* (strains CCMP 628, CCMP 627, CCMP 1528, CCMP 1524, SK 35, Palau, Santou (China)), *P. pouchetii* (SK 34 and SK 34 clone 3), *P. cordata* and *P. antarctica* (strains SK 20, SK 22, SK 23, CCMP 1374, DE2, T9-1, D4-5, A1-3 and T4-2). Only sequence positions marked in the weighting mask 1 were used for phylogenetic analysis in Fig. 6.

Some problems were encountered during the direct sequencing of ITS1. A clear sequence from warm-water *Phaeocystis* spp. was difficult to obtain because many ambiguities were generated in the sequencing reactions despite the use of amplification and sequencing primers specific for colonial Phaeo*cystis* species. Notably, ambiguities were found only in the ITS1 region and not in the 3' end of the 18S rRNA gene in warm-water Phaeocystis species. This suggests that different ITS1 copies may exist within a culture and were amplified and subsequently sequenced, thus causing the sequence to become unreadable once the multiple copies coincided in the sequence run. Sequences obtained from clone libraries made from a single strain of P. globosa from China were clearly different, documenting unequivocally that there is variation in the copies of the ITS in *P. globosa* and also *P. pouchetii* (Fig. 4*B*). In one strain of P. antarctica approximately 17

nucleotides at the 3' end of ITS1 region could not be determined (Fig. 5).

Based on our 18S rDNA analysis, we used P. cordata as outgroup to examine relationships among the colonial Phaeocystis spp. (Fig. 6) in the analysis of the ITS1 region using the positions marked by the weighting mask 1. All three colonial species are recovered in the three analyses. The clade containing all the cold-water isolates (P. antarctica and P. pouchetii) had strong bootstrap support (92-100% in the three analyses). The strains of P. globosa are very divergent from one another and the sequences from one strain did not fall together (Figs 5, 6). The warm-water clade (isolates of P. globosa) was only weakly supported in the bootstrap analyses (< 50, 50 and 94), with the highest bootstrap support coming from the maximum parsimony analysis in which the data were weighted by a re-scaled consistency index. Within

Fig. 6. Maximum likelihood tree inferred from ITS1 sequences from *P. globosa* (strains CCMP 628, CCMP 627 (multiple clones), CCMP 1528, CCMP 1524 (multiple clones), SK 35, Palau, Santou (multiple clones from China), *P. pouchetii* (SK 34 and SK 34 clone 3), *P. antarctica* (strains SK 20, SK 22, SK 23, CCMP 1374, DE2, T9-1, D4-5, A1-3 and T4-2) and *P. cordata* as outgroup. Only sequence positions marked in the weighting mask 1 (Fig. 5) were used for this phylogenetic analysis. Bootstrap values are placed at the nodes from a maximum likelihood analysis (100 replicates) a neighborjoining analysis (500 replicates). Scale bar corresponds to 10 changes per 100 nucleotide positions.

the cold-water complex, the two sequences of the single strain of *Phaeocystis pouchetii* fall together and are distinctly supported by the bootstrap analyses.

In contrast, we obtained only one sequence from each of the eight P. antarctica strains isolated from the water masses defined by the Antarctic continental boundary currents and they show a high degree of similarity (Table 2; Figs 5, 6). We feel that they can be separated into at least four different lineages if we analyse the Antarctic strains alone using nearly all ITS1 sequence data (see weighting mask 2) and P. pouchetii as an outgroup (Figs 4B, 6). The first divergence among the Antarctic clade is strain SK 22, which was isolated from the ACC. The second divergence is a strain from Prydz Bay (T4-2) and this is then followed by a nearly simultaneous divergence of the remaining strains. One divergence includes a cluster of strains from Prydz Bay (DE2, A1-3 and T9-1). The branching order of this cluster of strains from Prydz Bay is slightly different in Figs 4B and 6. The other divergence includes strain CCMP 1374 from the Ross Sea and two Phaeocystis strains from the Weddell Sea (SK 20, SK 23) (Figs 5, 6; Table 3) and finally strain D4-5 from Prydz Bay, which shares a last common ancestor with the Weddell Sea strain SK 23, as the final cluster to diverge among the Antarctic strains. Our initial PAUP analysis produced 42 equally parsimonious trees (CI = 0.94), which could not resolve any differences within the nine strains of P. antarctica because there were too few informative sites unless the data were weighted, in which case only one tree was produced. It did, however, consistently separate P. antarctica SK 22 and P. pouchetii as earlier divergences sister to the

Table 3. Description of sequence attributes in the ITS1 sequences of Phaeocystis species

Species and strains	Total length of ITS1	% G+C and (absolute no. of nucleotides)	No. of ambiguities
Phaeocystis antarctica SK 20	267	65.17 (174)	6
Phaeocystis antarctica SK 23	267	67.04 (179)	0
Phaeocystis antarctica CCMP 1374	267	65.92 (176)	2
Phaeocystis antarctica DE2	266	66.17 (176)	2

Phaeocystis globosa SK 35	288	68.40 (197)	0
Phaeocystis globosa P277	301	68.77 (207)	0
Phaeocystis globosa CCMP 1528	290	68.62 (199)	1
Phaeocystis globosa CCMP 1524	289	65.74 (190)	0
Phaeocystis cordata	256	60.55 (155)	9

^{*a*} Seventeen nucleotides at the 3' end could not be determined.

^b The 3' end was highly variable and not alignable.

remaining Antarctic strains. In the short fragment of the *rbc*S gene, strain SK 22 was more closely related to *P. pouchetii* with a single base substitution shared by *P. antarctica* strain (SK 22) and *Phaeocystis pouchetii*.

Discussion

Morphological features

A summary of the salient morphological features of the *Phaeocystis* species used in this study is presented in Table 1. Species can be separated by DNA genome size as well as by features and size of the colonies and by size of the scales on the flagellated stage and length of the flagella.

18S rRNA

The phylogenetic relationships inferred from the analysis of the 18S rRNA data set continue to support the differentiation of the three major colonial forms of *Phaeocystis* at the species level (Medlin et al., 1994). Each of these three major species (P. antarctica, P. pouchetii and P. globosa) is monophyletic in 18S rRNA analyses. Taken together with the morphological and genome size differences shown in Table 1, it seems unwise to lump them into a single taxon as has been suggested in the past based on morphological evidence (Sournia, 1988) and more recently by Gallagher (1998), based on a more conservative opinion of species boundaries as inferred from molecular data. Unfortunately, some morphological data overlap and other clear morphological support is needed. Perhaps ultrastructural detail, such as pyrenoid structure or flagellar roots, may be helpful in this respect. Zingone et al. (1999) have provided some morphological characters differentiating the unicellular species P. jahnii from the colonial ones. It can be inferred from the branching order in the rRNA tree that the colonial form is derived. Because viruses are known only to attack the flagellated, unicellular stages of Phaeocystis (Jacobsen et al., 1996), it is not unreasonable to hypothesize that the evolution of the colonial stage has resulted in prevention of viral control of bloom populations (see discussions in Hamm et al., 1999) until the colony matrix is broken down, presumably by bacterial activity.

RUBISCO

In comparison with the 18S rDNA data set for these species, the relationships recovered by the RUBISCO spacer showed less resolution (Fig. 3). There are more base substitutions separating the major clades in the rRNA tree than in the RUBISCO spacer tree but this represents a smaller fraction of the total bases compared. For example, in the rRNA tree, one of the Mediterranean isolates, P. cordata, is separated from the warm-water P. globosa complex by 24-38 nucleotides and from the cold-water P. antarctica/P. pouchetii complex by 17-22 nucleotides (Medlin et al., 1994; Lange, 1997). In the RUBISCO analysis, these same taxa are separated by 24 nucleotides, respectively representing a 2% difference in the rRNA gene and a 24% difference in the RUBISCO spacer. Variation in the 18S rRNA gene ranged from 6 to 12 base substitutions between P. globosa strains and P. antarctica/P. pouchetii strains, whereas in the RUBISCO spacer these taxa are identical. If we were to base our species level determination on the RUBISCO spacer alone, we would lump all the colonial species into one taxon.

The lack of variation in the RUBISCO spacer among well-defined Phaeocystis species was surprising in view of the amount of inter- and intraspecific variation reported in red algae (Maggs et al., 1992; Goff et al., 1994; Brodie et al., 1998; Zuccarello et al., 2000). The RUBISCO spacer was too highly conserved in Phaeocystis to be used for populationlevel studies or even to infer phylogenetic relationships between closely related colonial species because these sequences were identical. Even more surprising was the fact that 105 nucleotides in the *rbc*S gene were more informative than the spacer region and able to resolve differences among the colonial strains. The Prymnesiophyceae are a much younger group than the red algae, which may be an important factor in the lack of variation detected in this non-coding region among *Phaeocystis* species as was postulated for global isolates of the young species Emiliania huxleyi (250000 years) (Medlin et al., 1996). However, the high similarity among the four diatom taxa for which RUBISCO sequence data are available (Fig. 2) suggests that the RUBISCO spacer is also highly conserved among diatom genera as well. These diatom genera are very different morphologically and phylogenetically, ranging from the advanced nitzschioid Cylindrotheca to bipolar centrics, yet the RUBISCO spacer region among these taxa is very similar. Although we cannot be sure of the identification of the contaminant that we picked up in our RUBISCO sequencing, we suspect that it is the genus Chaetoceros. In field samples, small, unicellular Chaetoceros spp. often reside in or around Phaeocystis colonies and among the known diatom genera here Chaetoceros would be basal to the other three in a molecular analysis (Chesnick et al., 1997). An undetected diatom in the colony could explain the diatom-like pigment signature found in some Phaeocystis strains (Vaulot et al., 1994). Stache-Crain et al. (1997) also found the RUBISCO spacer useful only at the generic level in the Ectocarpales of the Phaeophyceae, another younger algal lineage. It may also be that, in these groups with little variation in the spacer, this region may be under some type of functional constraint (as yet unknown) that prevents it from evolving at a higher rate. Bailey & Andersen (1999) found no variation among multiple isolates of two pelagophytes and they interpreted this to infer that they had not uncovered any hidden varieties or cryptic species in the algae they examined.

ITS regions

The ITS regions in the warm-water species are highly variable and we have documented that there is variation in the copies of the ITS regions within a single strain. These non-homogeneous copies make interpretation of phylogenetic relationships among the warm water strains impossible. One possible explanation for the variable copies is that P. globosa is indeed a multi-species complex as indicated by the variation in DNA content among several strains and these species have hybridized with one another yielding heterozygous alleles for the ITS regions. In addition, the large divergence in the ITS region and the low to moderate bootstrap support among the strains of *P. globosa* support the earlier hypothesis (Vaulot et al., 1994) that P. globosa is actually a species complex (Table 2). Variable copies of the second intron region of the mini-collagen gene in mass spawning corals was taken as genetic evidence of recent hybridizations between coral species (Hatta et al., 1999) and variable copies of the ITS region have also been reported in the green algae Caulerpa taxifolia and C. racemosa (Jousson et al., 2000; Famà et al., 2000).

Interpretation of the phylogenetic relationships in the cold-water species was easier because only P. pouchetii exhibited variable copies of the ITS region within one strain. P. antarctica thus appears, based on clear ITS sequence, to contain only strains which have homogeneous ITS regions and we interpret this as support for a single species in Antarctic waters. It appears from our limited sampling around the Antarctic continent that the ITS1 region is suitable for resolving the biogeographic history of Phaeocystis, especially in the Antarctic. Populations of P. antarctica within the continental boundary water masses appear to be well mixed because currents around the Antarctic continent move rather quickly and may effectively act as a barrier to significant population structure. Strain SK 22 isolated within the ACC is clearly different. Our earlier hypothesis, proposed from rDNA data (Medlin et al., 1994), that ancestral populations in the Antarctic gave rise to present-day P. antarctica and P. pouchetii populations appears to be supported by our ITS1 analysis of the cold-water Phaeocystis strains. P. antarctica and P. pouchetii, both polar, are more closely related to one another than either is to the cold and warm-temperate to tropical populations of present-day P. globosa as supported in all our analyses from the two different regions/ genes. This suggests that dispersal did not occur from present-day warm-water populations into present-day cold-water populations and also that gene flow has occurred from pole to pole across tropical oceans. Arctic P. pouchetii populations thus probably arose by a dispersal event from the south to the north during colder climate periods that allowed populations to survive the crossing of equatorial waters, as has been documented for other organisms (Crame, 1993; Darling et al., 2000).

If we follow the branching order in Figs 1, 4B and 6, we can hypothesize the following scenario. It is clear from Fig. 1 that the ancestral populations in the Antarctic were derived from ancestors of the present-day warm-water species. Our own molecular clock calculations based on 18S rRNA sequence data calibrated with the fossil record from haptophyte coccolithophorid species indicate that the warm-water *Phaeocystis* species diverged from the cold water species approximately 30 Mya, which coincides with the time that the Drake passage opened and the ACC system was formed (Medlin et al., 1994). This would have effectively isolated ancestral populations in the Antarctic sufficiently to allow them to speciate from their warm-water ancestors. It can be inferred from Figs 4B and 6 that presumed descendants of these warm-water ancestors were first entrained in the ACC. Some of these ancestral populations must have been transported northward and across the Equator shortly after the Drake passage opened because the P. pouchettii populations are sister to the P. antarctica populations. The ACC today encircles the Antarctic continent every 1-2 years. Water is entrained from this current into the major gyres of the continental water masses (Treshnikov, 1964). Using the branching order in Fig. 4B we can trace the dispersal of the clones from the ACC, although the bootstrap support for the branching order among the clades is weak and even then only with the weighted maximum parsimony analysis. From Fig. 4B, the first entrainment with a bootstrap support of 99% appears to be into Prydz Bay, because strain T4-2 isolated from this bay is the first divergence in our tree. These populations then established themselves in the eastern Antarctic in Prydz Bay. Subsequent divergences in the tree indicate that populations were then entrained into the Ross Sea and almost simultaneously they were entrained into the Weddell Sea (bootstrap support 54%). Both isolates from the Weddell Sea were the last to diverge before the populations were again entrained back into Prydz Bay from populations in the Weddell Sea, because isolates from this bay are some of the last divergences in the tree (bootstrap support 54%). The distribution of these isolates in this fashion follows the predominant current patterns of surface waters in the Antarctic today. What we do not know is how different the surface-water circulation was 30 Mya ago before the ACC was established. What is clear from these data is that *P. antarctica* does not have variable copies of the ITS as do P. globosa and P. pouchetii. We infer from these data that the populations of the latter two may in fact represent more than one species, whereas *P. antarctica* is only one species because the Antarctic continental water masses have homogenized the populations.

Other studies have also shown the effect of mixing on the homogenization of the genetic structure of Antarctic populations. Antarctic krill species within the Antarctic continental water masses are very similar as documented by both mitochondrial DNA (T. Patarnello *et al.*, unpublished) and isozyme analysis (Fevolden & Schneppenheim, 1989). The mitochondrial DNA study also suggested that the formation of the ACC effectively isolated krill species in Antarctic water masses from those north of the ACC. Calculation of the time of divergence between species groups found either side of the ACC coincided with the timing of the ACC, approximately 30 Mya.

It is clear from our analyses of the ITS1 region from P. antarctica populations that modern-day dispersal of these populations in Antarctic continental waters follows the current circulation pattern of the ACC around the Antarctic and cladogenesis from warm-water ancestors was coincident with the opening of the Drake passage and the establishment of the ACC. Both polar populations are descended from a last common ancestor and we believe the dispersal from pole to pole occurred from south to north.

Acknowledgements

This work was supported by grants from the DFG (SM 22/5-1), the National Natural Science Foundations of China (No. 39970063), and Guangdong province (No. 001213); and the Red-tide Key Project (No. 011208). We thank Uschi Wellbrock and Dr W.H.C.F. Kooistra for technical assistance, and Professor R. Pienaar and H. Marchant and Drs D. Vaulot and A. Zingone for providing cultures of *Phaeocystis*. We would like to thank Drs K. Valentin and D. Bhattacharya for critically reading the manuscript.
